CARPENTER'S

PRINCIPLES

OF

HUMAN PHYSIOLOGY

EDITED BY

HENRY POWER, M.B. Lond., F.R.C.S.

MEMBER OF BOARD OF EXAMINERS IN ANATOMY AND PHYSIOLOGY, ROYAL COLLEGE OF SURGEONS, ENGLAND
LATE LECTURER ON PHYSIOLOGY AT THE WESTMINSTER HOSPITAL
OPHTHALMIC SURGEON TO ST. BARTHOLOMEW'S HOSPITAL
SURGEON TO THE ROYAL WESTMINSTER OPHTHALMIC HOSPITAL

Ninth Edition

LONDON
J. & A. CHURCHILL, NEW BURLINGTON STREET
1881

M15402

WELLCOME INSTITUTE LIBRARY
Coll. WellMOmec
Call No. QT104 1881 C29c

EDITOR'S PREFACE.

In the preparation of this Edition the general arrangement of the work has been preserved, except that the sections on Pathology have been condensed, partly with the view of reducing the size of the volume, and partly because large treatises are now devoted to this subject, which, when the earlier editions of the work were published, was still in its infancy. Every page has undergone revision, and to some paragraphs considerable additions have been made.

In Physiological Chemistry the standard works of Hoppe-Seyler and of Hofmann have been taken as guides; and the Editor regrets that the valuable treatise of Professor Gamgee appeared too recently to enable him to make use of it in the preparation of the sections on this subject.

In Histology the treatises of Ranvier, Frey, Toldt and Krause, and the excellent Atlas in course of publication by Klein and Noble Smith, have been chiefly consulted.

In the purely Physiological sections an endeavour has been made to introduce in short compass the results of the more important Physiological work that has been done during the last three or four years. The statements made have generally been taken from the original articles, but in some instances the careful abstracts contained in Schmidt's "Jahrbuch," the "Centralblatt für die Medicinischen Wissenschäften," and in the "Medical Record," have been taken as the authorities. The value of such abstracts, made by competent men, increases constantly with the ever-increasing number of journals and memoirs, which has now become so great as to render it almost impossible for the most indefatigable to read all. This is especially

the case with the long and exhaustive memoirs of the Germans, correct and short abstracts of which are particularly useful.

I have to thank my son, Mr. D'Arcy Power, for working up the chapter on Development, for revising many of the sheets, and for aid in completing the Index, which, it is hoped, will be found unusually complete and accurate.

The student must not expect to learn Physiology from such a work as this. Physiology is now, as Anatomy has always been, a practical subject, and just as a competent knowledge of Anatomy can only be acquired in the dissecting-room, so Physiology can only be learned in the laboratory. The institution of such laboratories by Sharpey, Foster, Sanderson, Rolleston, Rutherford, Gamgee, and many others, in connection with the universities or with medical schools, enables every one to commence the study of Physiology at the beginning under competent instruction, and by familiarizing himself with the simplest, prepare himself to understand the more complex phenomena of life. All who are practically engaged in teaching feel that a sound knowledge of the elementary truths of Physiology is of far greater value to the practitioner than a superficial and necessarily inaccurate acquaintance with the hypotheses that are constantly being advanced, and as constantly modified or subverted.

The performance of experiments on living animals, even of a painless nature, has been practically abolished by the Legislature, but there still remains in the investigation of the phenomena of Development, in those of Histology and of Physiological Chemistry, wide fields of research for the original investigator; and the observations of Darwin, Cohn, and others, show how much may be learnt from an examination of the life history of plants, and of the lower forms of animal life, that is interesting to the student of human Physiology. It is upon such foundation, the value of which has only recently been clearly perceived, that Physiology must rest; and the more certainly the elementary facts are known, the more reliable and satisfactory will be all subsequent work.

HENRY POWER.

TABLE OF CONTENTS.

CHAPTER I.

OF LIFE AND ITS CONDITIONS. PAGE 1

CHAPTER II.

OF THE DISTINCTIVE CHARACTERISTICS OF MAN. 15

CHAPTER III.

ON THE MINUTE ANATOMY OF THE CONNECTIVE TISSUES, CELLS, AND THEIR DERIVATIVES. 32

CHAPTER IV.

CHEMICAL COMPOSITION OF THE BODY. 58

CHAPTER V.

OF FOOD AND THE DIGESTIVE PROCESS.

1. Of Food and Drink, their Nature and Destination 92
2. Of Hunger and Thirst; Starvation 109
3. Movements of the Alimentary Canal 116
   - Prehension and Ingestion 116
   - Mastication 117
   - Deglutition 118
   - Movements of the Stomach 121
   - Peristaltic Movement of Intestines 125
   - Defecation 130
4. Of the Changes which the Food undergoes, during its passage along the Alimentary Canal 131
   - Salivary Secretion, and Buccal Digestion 132
   - Gastric Juice, and Gastric Digestion 141
   - Intestinal Digestion; Pancreatic Secretion 158
   - Biliary Secretion 164
   - Intestinal Secretion 168

CHAPTER VI.

OF ABSORPTION AND SANGUIFICATION.

PAGE
1. Of Absorption from the Digestive Cavity; Intestinal Villi 177
2. Absorption of Albumin 185
Of Fats 186
Of Carbohydrates 187
In Large Intestine 187
Through Skin 188
By Lymphatics 191
3. Of the Elaboration of the Nutrient Materials 192
Structure of Lymphatics and of Lymphatic Glands. 192
Structure of Serous Membranes 196
Assimilating action of Absorbent System 198
Composition and Properties of Chyle and Lymph 199
Causes of Movement of Lymph 204
Vascular or Ductless Glands 206
Spleen 207
Adrenals 212
Thymus 213
Thyroid 216

CHAPTER VII.

OF THE BLOOD; ITS PHYSICAL CHARACTERS, CHEMICAL COMPOSITION, AND VITAL PROPERTIES.

1. General Considerations:—Quantity of Blood 220
2. Of the Physical, Chemical, and Structural Characters of the Blood . . . 223
Corpuscular Elements of Blood 225
Spectrum Analysis of the Blood 239
Coagulation of the Blood 241
Development of Blood Corpuscles 251
Chemical Composition of the Blood 255
Pneumatology of the Blood 258
Alterations of the Composition of the Blood in Disease 264
3. Of the Vital Properties of the Blood, and its Relations to the Living Organism . 269

CHAPTER VIII.

OF THE CIRCULATION OF THE BLOOD.

1. Of the Circulation in General 270
2. Action of the Heart 275
Source of its Rhythmical Movements 276
Succession of its Actions 277
Sounds of the Heart 283
Force of the Heart 285
Action of Nervous System upon the Heart 285
Excito- or Cardio-motor System of the Heart 285
Effects of Variations of Temperature upon the Heart's Action . . . 288
Nerves Retarding or Inhibiting the Action of the Heart 290
Nerves Accelerating the Action of the Heart 295
Rate of its Pulsations 299
Circumstances Modifying the Action of the Heart 303

PAGE
3. Movement of the Blood in the Arteries 304
Pressure of the Blood in the Arteries 318
Rapidity of Movement of the Blood 323
4. Movement of the Blood in the Capillaries 326
Emigration of Corpuscles from Vessels 331
5. Movements of the Blood in the Veins 333
6. Peculiarities of the Circulation in different Parts 338

CHAPTER IX.

OF RESPIRATION.

1. Nature of the Function, and Provisions for its Performance 341
Sources of Production of Carbonic Acid in the Living Body 342
Structure of the Lungs 344
Mechanism of Respiration 349
Respiratory Movements 350
Muscles Effecting the Respiratory Movements 352
Relation of the Nervous System to the Respiratory Acts 356
2. Effects of Respiration on the Air 365
Circumstances affecting the Exhalation of Carbonic Acid Gas . . . 369
Exhalation and Absorption through the Lungs 382
3. Effects of Suspension or Deficiency of Respiration 387
Asphyxia 389
Predisposition to Zymotic Diseases 394

CHAPTER X.

OF NUTRITION.

1. General Considerations.—Formative Power of Individual Parts 396
2. Of the Balance of the Vital Economy 402
With Ordinary Diet 404
In Fasting 406
On Pure Meat Diet 409
On Meat and Fat Diet 410
On Meat and Starch or Sugar Diet 410
Disintegration of various Organic Compounds, with accompanying Development of Force 411
Absolute Amount of Work done in and by the Body 416
Degeneration of Tissues 418
3. Varying Activity of the Nutritive Processes 422
Hypertrophy; Tumours 422
Atrophy 424
Reparative Process 426

CHAPTER XI.

ON SECRETION AND EXCRETION.

1. Of Secretion in General 428
Excretory Operations 430
Metastasis of Secretion 431

PAGE

2. The Liver.—Secretion of Bile 433
Structure and Actions of the Liver 434
Composition and Sources of Bile 439
Spectrum of Bile 442
Origin of Bile 444
Influence of the Nervous System on the Secretion of Bile 446
Glycogenic Function of the Liver 447
3. The Kidneys.—Secretion of Urine 456
Structure and Actions of the Kidneys 457
Composition and Sources of Urine 468
4. The Skin.—Cutaneous Transpiration 489
Structure of Sudoriparous Glands 489
Sudoriparous Excretion 490

CHAPTER XII.

OF THE EVOLUTION OF HEAT, LIGHT, AND ELECTRICITY.

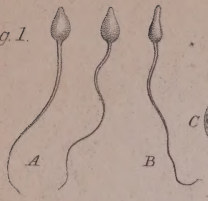
1. General Considerations 496
2. Evolution of Heat 498
Temperature of the Human Body 499
Sources of Calorifying Power 509
Absolute amount of Heat produced in the Body 513
Local Variations in the Production of Heat 515
3. Evolution of Light 519
4. Evolution of Electricity 520

CHAPTER XIII.

ON THE FUNCTIONS OF THE CEREBRO-SPINAL NERVOUS SYSTEM.

1. General Summary 523
Structure of the Nervous System 524
Regeneration of Nervous Tissue 528
Chemistry of Nervous Tissue 529
Cerebro-Spinal Nervous Centres 535
Cerebro-Spinal Nerve-trunks 541
Determination of the Functions of Nerves 544
Rapidity of Transmission of Motor and Sensory Impressions 551
Electrical Currents in Nerves 553
Electrotonus 556
Law of Muscular Contraction 562
2. Of the Spinal Axis (Spinal Cord and Medulla Oblongata) 564
Structure and Relations of the Spinal Cord 565
Nerves of the Spinal Axis 569
Deep Origin of Spinal Nerves 570
Structure and Relations of the Medulla Oblongata 573
Deep Origin of Nerves from Medulla Oblongata 579
The Spinal Cord as a Conductor of Sensory Impressions and Motor Impulses . 596
The Spinal Cord as an Independent Centre 602
Laws of Reflex Action 604
3. Of the Sensory Ganglia 617
Structure and Relations of the Sensory Ganglia 618
Nerves of Special Sensation 620

Fig. 1.



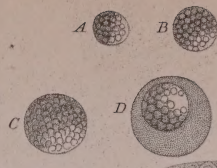


Fig. 2.

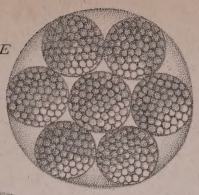

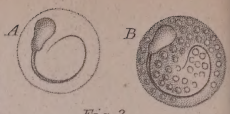

Fig. 3.

Fig. 4.

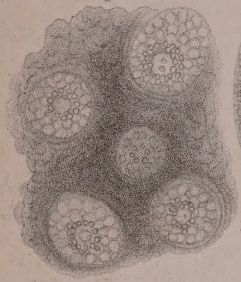

Fig. 6.

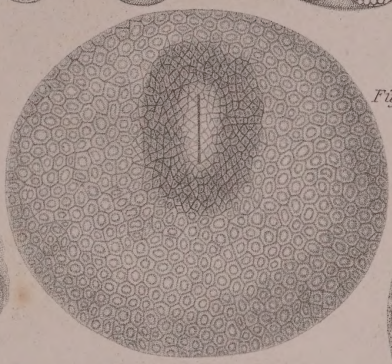

Fig. 5.

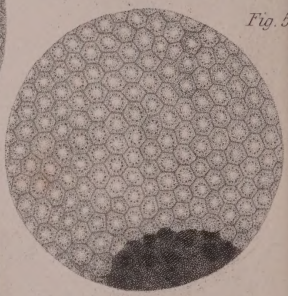

Fig. 7.

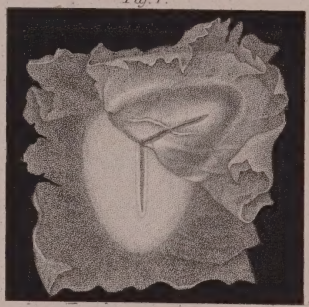

Fig. 8.

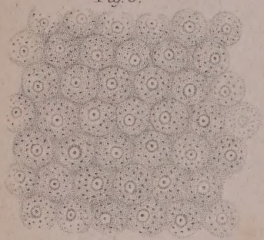

Fig. 9.

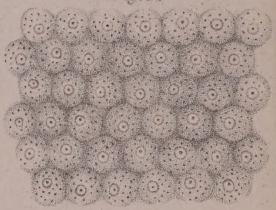

Fig. 10.

H. Adlard &c.

PAGE

Of the Sensory Ganglia—*continued.*
Nerves of Common Sensation 624
Functions of the Sensory Ganglia :—Sensori-Motor Actions 625
Muscular Sense 637
4. Of the Cerebellum 644
Structure and Relations of the Cerebellum 645
Functions of the Cerebellum.—Co-ordination of Muscular Action . . 646
Supposed relation to Sexual Propensity . . 651
5. Of the Cerebrum 657
Structure and Relations of the Cerebrum 659
Functions of the Cerebrum.—Intelligence as contrasted with Instinct . . 666
6. Of Sleep and its Allied States 681
Dreaming 690
Somnambulism, Spontaneous and Induced 692
Hypnotism 692

CHAPTER XIV.

OF SENSATION AND THE ORGANS OF THE SENSES.

1. Of Sensation in General 694
2. Sense of Touch 698
3. Sense of Taste 707
4. Sense of Smell 714
5. Sense of Vision 718
6. Sense of Hearing 759

CHAPTER XV.

ON THE STRUCTURE AND FUNCTIONS OF MUSCULAR TISSUE.

1. Structure of Muscular Tissue 780
2. Development of Muscular Tissue 790
3. Nutrition of Muscular Tissue 791
4. Phenomena accompanying Contraction 793
5. Electrical Relations of Muscle 796
6. Mechanism of Muscular Contraction 798
7. Rigor Mortis 809
8. Voluntary and Involuntary Movements 811
9. Symmetry and Harmony of Muscular Movements 813
Movements of Locomotion 813
Movements of the Eye ; Strabismus 817
10. Energy and Rapidity of Muscular Contraction 820
Absolute Force of Muscle 823

CHAPTER XVI.

OF THE VOICE AND SPEECH.

1. Of the Larynx and its Actions 826
2. Of Articulate Sounds 839
Stammering 844

CHAPTER XVII.

OF THE INFLUENCE OF THE NERVOUS SYSTEM ON THE ORGANIC FUNCTIONS.

PAGE
1. Sympathetic Nervous System; its Structure and Relations 845
2. Influence of Nervous Agency and of Mental States on Contractions of Organic Muscles 853
3. Influence of Nervous Agency and of Mental States on Nutrition and Secretion . 854

CHAPTER XVIII.

OF GENERATION.

1. General Character of the Function 864
2. Action of the Male 867
Structure of Testes.—Spermatic Fluid 868
Coitus; Emissio Seminis 873
3. Action of the Female 874
Structure of Ovary, Ovisac, and Ovum 875
Puberty; Menstruation 877
Maturation of Ova; Corpus Luteum 881
Fecundation of Ovum 885
Formation of Decidua 887
Formation of Placenta 889
Innervation of the Uterus 894
Parturition; Duration of Gestation 895
4. Development of the Embryo 907
5. Of Lactation 966

CHAPTER XIX.

OF THE DIFFERENT BRANCHES OF THE HUMAN FAMILY, AND THEIR MUTUAL RELATIONS.

1. General Considerations; Differentiation of Species 979
2. General Survey of the Principal Varieties of the Human Species 997

CHAPTER XX.

OF THE MODES OF VITAL ACTIVITY CHARACTERISTIC OF DIFFERENT AGES.

1. General Considerations; Germinal Capacity 1011
2. Period of Growth and Development 1013
3. Period of Maturity 1025
4. Period of Decline 1026

CHAPTER XXI.

OF DEATH. 1028

APPENDIX 1035

INDEX OF SUBJECTS AND OF AUTHORS REFERRED-TO. 1037

TABLE OF ILLUSTRATIONS.

PLATE I.

FIG.

1. Spermatozoa of Man; A, viewed on the surface; B, viewed edgeways (§ 690).

2. Vesicles of evolution from the seminal fluid of the Dog; A, B, C, single vesicles of different sizes; D, single vesicle within its parent-cell; E, parent-cell enclosing seven vesicles of evolution (§ 691).

3. Development of Spermatozoa within the vesicles of evolution: A, B, vesicles containing spermatozoa in process of formation; C, D, spermatozoa escaping from the vesicles (§ 691).

[The three preceding figures are after Wagner and Leuckardt ("Cyclop. of Anatomy and Physiology," Art. 'Semen.')]

4. Thin slice of the ovarium of a Sow three weeks old, showing the Graafian vesicles or ovisacs imbedded in a fibro-cellular stroma. The ovisacs are filled with cells, in the midst of which one large one may be especially distinguished; this, which is the germinal vesicle, is surrounded by minute granules, which constitute the first indication of the yolk (§ 696).

5. Ovum of a Rabbit, showing the vitelline mass almost entirely converted into distinct cells, of which those at the surface are pressed against each other and against the zona pellucida, so as to assume a hexagonal form. The dark portion consists of a mass of vitelline spheres, which has not undergone this conversion (§ 696).

6. Ovum of the Rabbit, seven days after impregnation, viewed on a black ground. The outer membrane is the chorion, on which are seen incipient villosities. Within this is the *blastodermic vesicle*, at the summit of which is the projection formed by the *area germinativa;* and from this, the mucous layer of the germinal membrane is seen to extend over about one-third of the surface of the contained yolk (§ 733).

7. Portion of the germinal membrane, taken from the *area germinativa*, to show the two layers of which it is composed; the *serous*, or animal layer (epiblast) is turned back, so as to show the *mucous* or vegetative layer (mesoblast and hypoblast) *in situ*. In the latter is seen the *primitive trace* (§ 733).

8. Portion of the *serous* layer of the germinal membrane, highly magnified; showing that it is made-up of nucleated cells, united by intercellular substance, and filled with minute molecules (§ 733).

FIG.

9. Portion of the *mucous* layer of the germinal membrane, highly magnified; showing that it is made-up of cells, whose borders are more distinct and more closely applied to each other than those of the serous layer, and whose contents are more transparent (§ 733).

[The six preceding figures are after Bischoff ("Entwickelungsgeschichte der Säugethiere," &c. (1842)—"das Kaninchen-eies"—(1842)—"des Hunde-eies" (1845).]

10. Gravid Uterus of a Woman who had committed suicide in the seventh week of pregnancy, laid open:—*a*, os uteri internum; *b*, cavity of the cervix; *c*, *c*, *c*, *c*, the four flaps of the body of the uterus turned back; *d*, *d*, *d*, inner surface of uterine decidua; *e*, *e*, decidua reflexa; *f*, *f*, external villous surface of the chorion; *g*, internal surface of the chorion; *h*, amnion; *i*, umbilical vesicle; *k*, umbilical cord; *l*, embryo; *m*, space between chorion and amnion (§ 710 *et seq.*). [After Wagner ("Icones Physiologicæ").]

PLATE II.

11. Uterine Ovum of Rabbit, showing the Area Pellucida, with the primitive trace (§§ 733, 734).

12. More advanced Ovum, showing the incipient formation of the Vertebral column, and the dilatation of the primitive groove at its anterior extremity (§ 733).

13. More advanced Embryo, seen on its ventral side, and showing the first development of the Circulating apparatus. Around the Vascular Area is shown the terminal sinus *a*, *a*, *a*. The blood returns from this by two superior branches, *b*, *b*, and two inferior, *c*, *c*, of the omphalo-mesaraic veins, to the heart, *d*; which is, at this period, a tube curved on itself, and presenting the first indication of a division into cavities. The two aortic trunks appear, in the abdominal region, as the inferior vertebral arteries, *e*, *e*; from which are given off the omphalo-mesaraic arteries, *f*, *f*, which form a network that distributes the blood over the vascular area. In the cephalic region are seen the anterior cerebral vesicles, with the two ocular vesicles, *g* (§ 735).

(The three preceding figures are from the works of Bischoff previously cited.]

PLATE III.

(To face page 28.)

Comparative View of the Skeleton of Man, and that of the Orang Outan. [After Owen ("Zoological Transactions," vol. i.).]

CHAPTER I.

OF LIFE, AND ITS CONDITIONS.

1. The term *Life* has been used by different writers, Physiological and Ontological, in a great variety of significations; but these are for the most part capable of reduction to three categories,—Life being regarded either (1) as the *aggregate of the phenomena* exhibited by any Organized being from the commencement to the conclusion of its individual existence, or (2) as the *mode of activity* peculiar to such beings, whereby they are distinguished from inanimate bodies, or (3) as the *special agency* supposed to be inherent in every organism, and to be the efficient cause alike of its first development and of its subsequent maintenance. The first is the sense in which the term is understood by Philosophers of the 'positive' school, who refuse to concern themselves with anything save phenomena that are immediately cognizable by the senses: while the last is the meaning attached to it by such as think that a great deal of trouble is saved by the assumption of a hypothetical entity, whose agency may at once account for everything not to be otherwise explained. To both these definitions it may be objected that they tend to limit inquiry into the essential nature of Vital Action. For by taking the former as a starting-point, we are led to fix our attention too exclusively on the *material conditions* presented in the structure of the Organism, and to ignore the *forces* by which its activity is maintained: just as if, in studying the operations of a Cotton-factory, we were to limit our attention to the mechanism of the carding, spinning, weaving, and other machines by whose instrumentality its products are elaborated, and were to neglect, as a condition not directly cognizable by our senses, the Motive Power without which those machines would all be inert. On the other hand, by resting in the assumption of a "Vital Principle" or "Organic Agent" as affording a sufficient account of all that is mysterious in the nature of Life, we really remove it from the domain of scientific inquiry; just as if the visitor to a Cotton-factory were to give up in despair any attempt to acquaint himself with the meaning of the several processes that go on before his eyes, and were to regard it as a sufficient account of the transformation of raw cotton into woven calico, that it takes place by the agency of a "calico-making principle."

2. But if, on the other hand, the Physiologist takes as his stand-point the conception of Life as *a peculiar mode of activity*, he at once finds himself on a pathway of inquiry marked out for him by the antecedent researches of the Physical philosopher. For as, in the study of that great cycle of mutually-related changes which may be designated the Life of the Universe, the Physicist has been led in the first instance to recognise several distinct modes of activity, *e.g.*, Mechanical and Chemical, Electrical and Thermal; and then, prosecuting his analysis under the guidance of that idea of Power which he finds in his own sense of effort, has been brought to refer every effect to a causative Force of some kind, acting through a certain Material instrumentality:—so the Physio-

logist who makes the living Organism his study, is led in the first place to refer its peculiar phenomena to a set of categories as distinct from the preceding as they are from each other; and thence to distinguish between their *instrumental* and their *dynamical* conditions, the Organic Structure and the Vital Forces which animate it. But further, as the Physicist, in proportion to the elevation of his stand-point and the comprehensiveness of the survey he can thence take of the phenomena of the Inorganic Universe, is enabled to discern, first the mutual relation, and at last the essential unity, of all those Forces whose manifestations appeared so diverse when separately contrasted: so may the Physiologist, in proportion to the insight he gains into the peculiar characteristics of Vital Activity, come in the first instance to recognise the mutual relation of the agencies which underlie its diversified phenomena, next to perceive their fundamental unity as so many expressions of one and the same Vital Force acting through different material instrumentalities, and finally to discern the essential identity of this Force with that which maintains the ceaseless cycle of activity in the Universe at large.*

3. If, now, we inquire what it is that essentially distinguishes Vital from every kind of Physical Activity, we find this distinction most characteristically expressed in the fact, that a germ endowed with Life develops itself into an Organism of a type resembling that of its parent; that this organism is the subject of incessant changes, which all tend in the first place to the evolution of its typical form, and subsequently to its maintenance in that form, notwithstanding the antagonism of Chemical and Physical agencies which are continually tending to produce its disintegration; but that, as its term of existence is prolonged, its conservative power declines, so as to become less and less able to resist these disintegrating forces, to which it finally succumbs, leaving the organism to be resolved by their agency into the components from which its materials were originally drawn. The history of a Living Organism, then, is one of *incessant change*;† and the conditions of this change are to be found partly in the organism itself, and partly in the external agencies to which it is subjected.

4. But the Life of any complex organism, such as that of Man, is the aggregate of the Vital Activity of all its component parts; and we must ascertain the conditions on which the activity of each of these is dependent, before we can rightly comprehend their united action in the Life of the whole. No fact has been more clearly ascertained by modern Physiological research than this,—that as the germ derives from its parent certain independent endowments, in virtue of which it is enabled to develop itself (under appropriate conditions) into an organism which may be composed of a vast number of dissimilar parts,

* See the Author's Memoir 'On the Mutual Relations of the Vital and Physical Forces,' in the "Philosophical Transactions" for 1850.

† If change be essential to our idea of Life, it may be asked what is the condition of a Seed, which may remain unaltered during a period of many centuries, vegetating at last, when placed in favourable circumstances, as if it had only ripened the year before. We can scarcely call it *alive*, for it is not performing any vital operation. But it is not *dead;* for it has undergone no disintegration, and retains its *capacity for living*, which is analogous to the *potential energy* of the Physicist. The most correct designation of such a state (which can only be maintained under a complete seclusion from disintegrating agencies) seems to be *dormant vitality*. Certain Animals may be reduced to it; as the Frog by cold, and the Wheel-animalcule by slow desiccation. Organisms capable of undergoing such a suspension of activity may be kept in a dormant condition so long as disintegrating agencies are excluded; but the very conditions (as heat in the one case, moisture in the other, and both combined in the case of the seed) whose presence is followed by the renewal of active life if the organism has undergone no injurious change, insure its speedy decay if it be not able to resume its proper vital activity.

so each of those parts derives from the germ in which it had its origin an independent capacity for development and maintenance, in virtue of which it goes through its own course of vital activity, and by the ultimate cessation of which its own term of existence is limited. Of this mutual independence we have illustrations in the persistence of the 'molecular life' of individual parts long after 'somatic' death (or death of the body as a whole) has taken place;—in the fact that not only may vital activity be sustained in a part completely separated from the body by the maintenance of the circulation of blood through it, but vital endowments which had partially or completely ceased to manifest themselves in consequence of the cessation of the circulation, may be restored by its re-establishment;—and in the occasional reunion of members which have been entirely separated. But notwithstanding the wonderful diversity of structure and of endowments which we meet with in the study of any such complex organism, we encounter a harmonious unity or co-ordination in its entire aggregate of actions, which is yet more wonderful. It is in this harmony of co-ordination, whose tendency is to the conservation of the organism, that the state of Health or Normal Life essentially consists. And the more profound is our investigation of its conditions, the more definite becomes the conclusion to which we are led by the study of them,—that it is fundamentally based on the common origin of all these diversified parts in the same germ; the vital endowments of which, equally diffused throughout the whole fabric in those lowest forms of organization in which every part is but a repetition of every other, are differentiated in the highest amongst a variety of organs or instrumental structures more or less dissimilar, acquiring in virtue of this differentiation a much greater intensity.

5. In the lowest forms of Vegetable life, the primordial germ multiplies itself by duplicative subdivision into an apparently unlimited number of cells, each of them similar to every other, and capable of maintaining its existence independently of them. And in that lowest (Rhizopod) type of Animal life, the knowledge of which is among the most remarkable fruits of modern biological research, "the Physiologist has a case in which those vital operations which he is elsewhere accustomed to see carried on by an elaborate apparatus, are performed without any special instruments whatever; a little particle of apparently homogeneous jelly changing itself into a greater variety of forms than the fabled Proteus, laying hold of its food without members, swallowing it without a mouth, digesting it without a stomach, appropriatiug its nutritious material without absorbent vessels or a circulating system, moving from place to place without muscles, feeling (if it has any power to do so) without nerves, propagating itself without genital apparatus, and not only this, but in many instances forming shelly coverings of a symmetry and complexity not surpassed by those of any testaceous animals;"* whilst the mere separation of a fragment of this jelly is sufficient to originate a new and independent organism, so that any number of these beings may be produced by the successive detachment of such particles from a single Rhizopod, each of them retaining (so far as we have at present the means of knowing) the characteristic endowments of the stock from which it was an offset.

6. When, on the other hand, we watch the evolution of any of the higher types of Organization, whether Vegetable or Animal, we observe that although in the first instance the primordial cell multiplies itself by duplicative subdivision into an aggregation of cells which are apparently but repetitions of itself and of each other, this homogeneous extension has in each case a definite

* See the Author's "Introduction to the Study of the Foraminifera," published by the Ray Society, 1862, Preface, p. vii.

limit, speedily giving place to a structural differentiation which becomes more and more decided with the progress of development; until, in that most heterogeneous of all types—the Human Organism—no two parts are precisely identical, except those which correspond to each other on the opposite sides of the body. With this structural differentiation is associated a corresponding differentiation of function; for whilst in the Life of the most highly-developed and complex organism, we witness no act which is not foreshadowed, however vaguely, in that of the lowest and simplest, yet we observe in it that same "division of labour" which constitutes the essential characteristic of the highest grade of Civilization. For in what may be termed the elementary form of Human Society, in which every individual relies upon himself alone for the supply of all his wants, no greater result can be attained by the aggregate action of the entire community, than its mere maintenance; but as each individual selects a special mode of activity for himself, and aims at improvement in that speciality, he finds himself attaining a higher and yet higher degree of aptitude for it; and this specialization tends to increase as opportunities arise for new modes of activity, until that complex fabric is evolved which constitutes the most developed form of the Social State, wherein every individual finds the work—mental or bodily—for which he is best fitted, and in which he may reach the highest attainable perfection; while the mutual dependence of the whole (which is the necessary result of this specialization of parts) is such that every individual works for the benefit of all his fellows, as well as for his own. As it is only in such a state of Society that the greatest triumphs of Human ability become possible, so it is only in the most differentiated types of Organization that Vital Activity can present its highest manifestations. In the one case as in the other does the result depend upon a process of gradual *development*, in which, under the influence of agencies whose nature constitutes a proper object of scientific inquiry, that *most general* form in which the fabric—whether Corporeal or Social—originates, evolves itself into that *most special* in which its development culminates. And hence we are distinctly justified in the conclusion, that the special endowments of the several components of the organism, however dissimilar to each other, are nothing else than differentiated and proportionately intensified expressions of those which are common to every part of the originally homogeneous fabric;—a conclusion which derives a remarkable confirmation from the indication afforded by the phenomenon of 'Metastasis of Secretion,' that the general structure, even in the most highly-specialized organism, retains somewhat of its primitive community of function.

7. Thus, then, we may take that mode of Vital Activity which manifests itself in the Evolution of the germ into the complete organism repeating the type of its parent, and in the subsequent maintenance of that organism in its integrity,—in both cases at the expense of materials derived from external sources,—as the most universal and most fundamental characteristic of Life; and we have now to consider the nature and source of the Force or Power by which that evolution is brought about. The prevalent opinion has until lately been, that this power is inherent in the germ; which has been supposed to derive from its parent not merely its material substance, but a *nisus formativus*, *bildungs-trieb*, or *germ-force*, in virtue of which it builds itself up into the likeness of its parent, and maintains itself in that likeness until the force is exhausted, at the same time imparting a fraction of it to each of its progeny. In this mode of viewing the subject, all the organizing force required to build up an Oak or a Palm, an Elephant or a Whale, must be concentrated in a minute particle only discernible by microscopic aid; and

the aggregate of all the germ-forces appertaining to the descendants, however numerous, of a common parentage, must have existed in their original progenitors. Thus, in the case of the successive viviparous broods of *Aphides*, a germ-force capable of organizing a mass of living structure, which would amount (it has been calculated*) in the tenth brood to the bulk of 500 millions of stout men, must have been shut up in the single individual, weighing perhaps the 1-1000th of a grain, from which the first brood was evolved. A more complete *reductio ad absurdum* can scarcely be brought against any hypothesis; and we may consider it proved that, in some way or other, fresh organizing force is constantly being supplied *from without* during the whole period of the exercise of its activity. When we carefully look into the question, we find that what the *germ* really supplies is not the force, but the *directive agency;* thus rather resembling the control exercised by the superintendent builder who is charged with the working-out the design of the architect, than the bodily force of the workmen who labour under his guidance in the construction of the fabric. The actual constructive force, as we learn from an extensive survey of the phenomena of life, is supplied by Heat; the influence of which upon the rate of growth and development, both Animal and Vegetable, is so marked as to have universally attracted the attention of Physiologists; who, however, have for the most part only recognised in it a *vital stimulus* that calls forth the latent power of the germ, instead of looking upon it as itself furnishing the power that does the work.— It has been from the narrow limitation of the area over which Physiological research has been commonly prosecuted, that the intimacy of this relationship between Heat and the Organizing force has not sooner become apparent. Whilst the vital phenomena of Warm-blooded Animals, which possess within themselves the means of maintaining a constant temperature, were made the sole, or at any rate the chief objects of study, it was not likely that the inquirer would recognise the full influence of external Heat in accelerating, or of Cold in retarding, their functional activity. It is only when the survey is extended to Cold-blooded Animals, and to Plants, that the immediate and direct relation between Heat and Vital Activity, as manifested in the rate of growth and development, or of other changes peculiar to the living body, is unmistakably manifested. To some of those phenomena which afford the best illustrations of the mode in which Heat acts upon the living organism, attention will now be directed.

8. The agency of Heat as the 'efficient cause' or 'motive power' to which the phenomena of growth and development are to be referred, is peculiarly well seen in the process of Germination. The Seed consists of an embryo which has already advanced to a certain stage of development, and of a store of nutriment laid-up as the material for its further evolution; and in the fact that this evolution is carried on at the expense of organic compounds already prepared by extrinsic agency, until (the store of these being exhausted) the young plant is sufficiently far advanced in its development to be able to elaborate them for itself, the condition of the germinating embryo resembles that of an Animal. Now the seed, as already pointed out (§ 3, note), may remain (under favourable circumstances), in a state of absolute inaction during an unlimited period. If secluded from the free access of air and moisture, and kept at a low temperature, it is removed from all influences that would on the one hand occasion its disintegration, or on the other would call it into active life. But when again exposed to air and moisture, and

* See Prof. Huxley on the 'Agamic Reproduction of Aphis,' in "Linnæan Transactions," vol. xxii. p. 215.

subjected to a higher temperature, it either germinates or decays, according as the embryo it contains has or has not preserved its vital endowments,—a question which only experiment can resolve. The process of germination is by no means a simple one. The nutriment stored up in the seed is in great part in the condition of insoluble starch; and this must be brought into a soluble form before it can be appropriated by the embryo. The metamorphosis is effected by the agency of a ferment termed *diastase;* which is laid-up in the immediate neighbourhood of the embryo, and which, when brought to act on starch, converts it in the first instance into soluble dextrine, and then (if its action be continued) into sugar. The dextrine and sugar, combined with the albuminous and oily compounds also stored-up in the seed, are taken up by a process of intussusception contrasting strongly with the growth by apposition which characterizes the increase of a crystal, and form the 'protoplasm' which is the substance immediately supplied to the young plant as the material of its tissues; and the conversion of this protoplasm into various forms of organized tissue, which become more and more differentiated as development advances, is obviously referable to the vital activity of the germ. Now it can be very easily shown experimentally that the *rate of growth* in the germinating embryo is so closely related (within certain limits) to the amount of Heat supplied, as to place its dependence on that agency beyond reasonable question; so that we seem fully entitled to say that Heat, acting through the germ, becomes the constructive force or power by which the Vegetable fabric is built up.* But there appears to be another source of that power in the Seed itself. In the conversion of the insoluble starch of the Seed into sugar, and probably also in a further metamorphosis of a part of that sugar, a large quantity of carbon is eliminated, by combining with the oxygen of the air so as to form carbonic acid; this combination is necessarily attended with a disengagement of heat, which becomes very sensible when (as in malting) a large number of germinating seeds are aggregated together; and it cannot but be regarded as probable that the heat thus evolved within the seed concurs with that derived from without, in supplying to the germ the force that promotes its evolution.

9. The condition of the Plant which has attained a more advanced stage of its development, differs from that of the germinating embryo essentially in this particular, that the organic compounds which it requires as the materials of the extension of the fabric are formed by itself instead of being supplied to it from without. The tissues of the green surfaces of the leaves and stems, when acted on by light, have the peculiar power of generating at the expense of carbonic acid, water, and ammonia, various ternary and quarternary organic compounds, such as chlorophyll, starch, oil, and albumen; and of the compounds thus generated, some are appropriated by the constructive force of the Plant (derived from the heat with which it is supplied) to the formation of new tissues, whilst others are stored up in the cavities of those tissues, where they ultimately serve either for the evolution of parts subsequently developed, or for the nutrition of Animals which employ them as food. Of the source of those peculiar affinities by which the components of the Starch, Albumen, &c. are brought together, we have no

* The effect of Heat is doubtless manifested very differently by different seeds; such variations being partly *specific*, partly *individual*. But these are no greater than we see in the Inorganic world; the increment of temperature and the augmentation of bulk exhibited by different substances when subjected to the same absolute measure of heat, being as diverse as the substances themselves.—The whole process of 'malting,' it may be remarked, is based on the average regularity with which the seeds of a particular species may be at any time forced to a definite rate of germination by a definite increment of temperature.

right to speak confidently; but looking to the fact that these compounds are not produced in any case by the direct union of their elements, and that a decomposition of binary compounds seems to be a necessary antecedent of their formation, it is scarcely improbable that, as suggested by Prof. Le Conte,* that source is to be found in the chemical forces set free in the preliminary act of decomposition, in which the elements would be liberated in that 'nascent condition' which is well known to be one of peculiar energy. The influence of Light, then, upon the Vegetable organism appears to be essentially exerted in bringing about what may be considered a higher mode of chemical combination between oxygen, hydrogen, and carbon, with the addition of nitrogen, in certain cases; and there is no evidence that it extends beyond this. That the appropriation of the materials thus prepared, and their conversion into organized tissue in the operations of growth and development, are dependent on the agency of Heat, is just as evident in the stage of maturity as in that of germination. And there is reason to believe, further, that an additional source of Organizing force is to be found in the retrograde metamorphosis of organic compounds that goes on during the whole life of the plant; of which metamorphosis the expression is furnished by the production of carbonic acid. This is peculiarly remarkable in the case of the *Fungi*, which being incapable of forming new compounds under the influence of light, are entirely supported by the organic matters they absorb; corresponding in this respect on the one hand with the germinating Plant-embryo, and on the other with Animals. Such a decomposition of a portion of the absorbed material is the only conceivable source of the large quantity of carbonic acid they are constantly giving out; and it would not seem unlikely that the force supplied by this retrogade metamorphosis of the superfluous components of their food, which fall down (so to speak) from the elevated plane of 'proximate principles' to the lower level of comparatively simple binary compounds, constitutes the power by which another portion is raised to the rank of living tissue; thus accounting in some degree for the very rapid growth for which this tribe of Plants is so remarkable. This exhalation of carbonic acid, however, is not peculiar to Fungi and germinating embryos; for it takes place during the whole life of Flowering Plants, both by day and by night, in sunshine and in shade, and from their green as well as from their dark surfaces. It is not improbable that, as in the case of the Fungi, the source of this exhalation lies partly in the Organic matter absorbed; Plants being able to take up and assimilate soluble *humus*, which, being a more highly carbonized substance than starch, dextrine, or cellulose, can only be converted into compounds of the latter kind by parting with some of its carbon.† But it may also take place at the expense of compounds previously generated by the Plant itself, and stored up in its tissues, of which we seem to have an example in the unusual production of carbonic acid, which takes place at the period of flowering, especially in such plants as have a fleshy disk or receptacle containing a large quantity of starch; and thus, it may be surmised, an extra supply of force is provided for the maturation of those generative products, whose preparation seems to be the highest expression of the vital power of the Vegetable Organism.

10. The entire aggregate of Organic compounds contained in the Vegetable tissues, then, may be considered as the expression not merely of a

* See his very suggestive Memoir 'On the Correlation of Physical, Chemical, and Vital Force,' in the "Philosophical Magazine" for 1860, vol. xix. Ser. iv. p. 137.

† See the Memoir of M. Risler, 'On the Absorption of Humus,' in the "Bibliothèque Universelle," N.S., 1858, tom. i. p. 305.

certain amount of the *material elements* oxygen, hydrogen, carbon, and nitrogen derived (directly or indirectly) from the water, carbonic acid, and ammonia of the atmosphere, but also of a certain amount of *force* which has been exerted in raising these from the lower plane of simple binary compounds to the higher level of complex 'proximate principles;' whilst the portion of these actually converted into organized tissue may be considered as the expression of a further measure of force, which, acting under the directive agency of the germ, has served to build up the fabric in its characteristic type. This *constructive* action goes on during the whole Life of the Plant, which essentially manifests itself either in the extension of the original fabric (to which in many instances there seems no determinate limit), or in the production of the germs of new and independent organisms.—It is interesting to remark that the development of the more permanent parts involves the successional decay and renewal of parts whose existence is temporary; the 'fall of the leaf' being the effect, not the cause, of the cessation of that peculiar functional activity of its tissues, which consists in the elaboration of the nutritive material required for the production of wood. And it would seem as if the duration of the existence of such temporary parts stands in an inverse ratio to the energy of their action; the leaves of "evergreens," which are not cast off until the appearance of a new succession, effecting their functional changes at a much less rapid rate than do those of "deciduous" trees, whose term of life is far more brief.

11. Thus the final cause or purpose of the whole Vital Activity of the Plant, so far as the *individual* is concerned, is to produce an indefinite extension of the dense, woody, almost inert, but permanent portions of the fabric, by the successional development, decay, and renewal of the soft, active, and transitory cellular parenchyma; and, according to the principles already stated, the descent of a portion of the materials of the latter to the condition of binary compounds, which is manifested in the largely increased exhalation of carbonic acid that takes place from the leaves in the later part of the season, comes to the aid of external Heat in supplying the force by which another portion of those materials is raised to the condition of organized tissue.—The vital activity of the Plant, however, is further manifested in the provision made for the propagation of its race by the production of the germs of new individuals; and here, again, we observe that whilst a higher temperature than that which suffices to sustain the ordinary processes of vegetation, is usually required for the development of the flower and the maturation of the seed, a special provision appears to be made in some instances for the evolution of force in the sexual apparatus itself, by the retrograde metamorphosis of a portion of the organic compounds prepared by the previous nutritive operations. This seems the nearest approach presented in the Vegetable organism, to what we shall find to be an ordinary mode of activity in the Animal. That the performance of the generative act involves an extraordinary expenditure of Vital force, appears from this remarkable fact, that blossoms which wither and die as soon as the ovules have been fertilized, may be kept fresh for a long period if fertilization be prevented by cutting off the stamens before the bursting of the anthers.*

12. We are now prepared to inquire into the manifestations of Vital Activity in the Animal, and into the sources of the power by which the various forms of that activity are sustained. The first of these manifestations is, as in the Plant, the building up of the organism by the appropriation of

* On this subject see Herbert Spencer, "Principles of Biology," 1867, vol. ii. p. 419-470.

material supplied from external sources under the directive agency of the germ. The ovum of the Animal, like the seed of the Plant, contains a store of appropriate nutriment previously elaborated by the parent; and this store suffices for the development of the embryo, up to the period at which it can obtain and digest alimentary materials for itself. That period occurs in the different tribes of animals at very dissimilar stages of the entire developmental process. In many of the lower classes, the embryo comes forth from the egg, and commences its independent existence, in a condition which, as compared with the adult form, would be as if a Human embryo were thrown upon the world to obtain its own subsistence only a few weeks after conception; and its whole subsequent growth and development take place at the expense of the nutriment which the embryo ingests for itself. We have examples of this in the class of Insects, many of which come forth from the egg in the state of extremely simple and minute worms, having scarcely any power of movement, but an extraordinary voracity. The eggs having been deposited in situations fitted to afford an ample supply of appropriate nutriment (those of the flesh-fly, for example, being laid in carcases, and those of the cabbage-butterfly upon cabbage-leaves), each larva on its emersion is as well provided with alimentary material as if it had been furnished with a large supplemental yolk of its own; and by availing itself of this, it speedily grows to many hundred or even many thousand times its original size, without making any considerable advance in development. But having thus laid up in its tissues a large additional store of material, it passes into a state which, so far as the external manifestations of life are concerned, is one of torpor, but which is really one of great developmental activity; for it is during the *pupa* state that those new parts are evolved, which are characteristic of the perfect Insect, and of which scarcely a trace was discoverable in the larva; so that the assumption of this state may be likened in many respects to a re-entrance of the larva into the ovum. On its termination, the Imago or perfect Insect comes forth complete in all its parts, and soon manifests the locomotive and sensorial powers by which it is specially distinguished, and of which the extraordinary predominance seems to justify our regarding Insects as the types of purely *Animal* life. There are some Insects whose Imago-life has but a very short duration, the performance of the generative act being apparently the only object of this stage of their existence: and such for the most part take no food whatever after their final emersion, their vital activity being maintained, for the short period it endures, by the material assimilated during their larva state.* But those whose period of activity is prolonged, and upon whose energy there are extraordinary demands, are scarcely less voracious in their Imago than in their Larva-condition; the food they consume not being applied to the *increase* of their bodies, which grow very little after the assumption of the imago-state, but chiefly to their *maintenance*,—no inconsiderable portion of it, however, being appropriated in the female to the production of ova, the entire mass of which deposited by a single individual is sometimes enormous. That the performance of the generative act involves not merely a consumption of Material, but a special expenditure of Force, appears from a fact to be presently stated, corresponding to that already noticed (§ 11) in regard to Plants.

13. Now if we look for the source of the various kinds of Force,—which

* It is not a little curious that in the tribe of *Rotifera*, or Wheel-animalcules, all the males yet discovered are entirely *asplanchnic:* not only the whole of their development within the egg, but the whole of their active life after their emersion from it, being carried on at the expense of the store of yolk provided by the parent.

may be distinguished as constructive, sensori-motor, and generative,—that are manifested in the different stages of the life of an Insect, we find them to lie, on the one hand, in the Heat with which the organism is supplied from external sources, and, on the other, in the Food provided for it. The agency of heat, as the moving power of the constructive operations, is even more distinctly shown in the development of the Larva within the egg, and in the development of the Imago within its pupa-case, than it is in the germinating seed; the rate of each of these processes being strictly regulated by the temperature to which the organism is subjected. Thus ova which are ordinarily not hatched until the leaves suitable for the food of their larva have been put forth, may be made, by artificial heat, to produce a brood in the winter; whilst, on the other hand, if they be kept at a low temperature, their hatching may be retarded almost indefinitely without the destruction of their vitality. The same is true of the pupa-state; and it is remarkable that during the latter part of that state, in which the developmental process goes on with extraordinary rapidity, there is in certain Insects a special provision for an elevation of the temperature of the embryo by a process resembling incubation. Whether, in addition to the heat imparted from without, there is any addition of force developed within (as in the germinating seed) by the return of a part of the organic constituents of the food to the condition of binary compounds, cannot at present be stated with confidence: the probability is, however, that such a retrograde metamorphosis does take place, adequate evidence of its occurrence during the incubation of the Bird's egg being afforded by the liberation of carbonic acid which is there found to be an essential condition of the developmental process. During the larva-state there is very little power of maintaining an independent temperature, so that the sustenance of Vital Activity is still mainly due to the heat supplied from without.—But in the active state of the perfect Insect there is a *production of heat* quite comparable to that of warm-blooded animals; and this is effected by the retrograde metamorphosis of certain organic constituents of the food, of which we find the expression in the exhalation of carbonic acid and water. Thus the food of Animals becomes an internal source of heat, which may render them independent of external temperature.—Further, a like retrograde metamorphosis of certain constituents of the food is the source of that *sensori-motor power* which is the peculiar characteristic of the Animal organism; for on the one hand the demand for food, on the other the amount of metamorphosis indicated by the quantity of carbonic acid exhaled, bear a very close relation to the quantity of that power which is put forth. This relation is peculiarly manifest in Insects, since their conditions of activity and repose present a greater contrast in their respective rates of metamorphosis, than do those of any other animals.—Of the exercise of *generative* force we have no similar measure; but that it is only a special modification of ordinary vital activity appears from this circumstance, that the life of those Insects which ordinarily die very soon after sexual congress and the deposition of the ova, may be considerably prolonged if the sexes be kept apart so that congress cannot take place. Moreover, it has been shown by recent inquiries into the Agamic reproduction of Insects and other animals, that the process of Generation differs far less from those Reproductive acts which must be referred to the category of the ordinary Nutritive processes, than had been previously supposed.

14. Thus, then, we find that in the Animal organism the demand for food has reference not merely to its use as a *material* for the construction of the fabric; food serves also as a generator of *force;* and this force may be of

various kinds,—Heat and Motor-power being the principal but by no means the only modes under which it manifests itself. We shall now inquire what there is peculiar in the sources of the Vital Force which animates the organisms of the higher animals at different stages of Life.

15. That the Developmental force which occasions the evolution of the germ in the higher Vertebrata is really supplied by the heat to which the ovum is subjected, may be regarded as a fact established beyond all question. In the Frog and other Amphibia, which have no special means of imparting a high temperature to their eggs, the rate of development (which in the early stages can be readily determined with great exactness) is entirely governed by the degree of warmth to which the ovum is subjected. But in Serpents there is a peculiar provision for supplying heat; the female performing a kind of incubation upon her eggs, and generating in her own body a temperature much above that of the surrounding air.* In Birds, the developmental process can only be maintained by the steady application of external warmth, and this to a degree much higher than that which is needed in the case of cold-blooded animals; and we may notice two results of this application as very significant of the dynamical relation between Heat and Developmental Force,—first, that the period required for the evolution of the germ into the mature embryo is nearly constant, each species having a definite period of incubation,—and second, that the grade of development attained by the embryo before its emersion is relatively much higher than it is in cold-blooded vertebrata generally; the only instances in which anything like the same stage is attained without a special incubation being those in which (as in the Turtle and Crocodile) the eggs are hatched under the influence of a high external temperature. This higher development is attained at the expense of a much greater consumption of nutrient material; the store laid up in the 'food yolk' and 'albumen' of the Bird's egg being many times greater in proportion to the size of the animal which laid it, than that contained in the whole egg of a Frog or a Fish. There is evidence in that liberation of carbonic acid which has been ascertained to go on in the egg (as in the germinating seed) during the whole of the developmental process, that the return of a portion of the organic substances provided for the sustenance of the embryo, to the condition of simple binary compounds, is an essential condition of the process; and since it can scarcely be supposed that the object of this metamorphosis can be to furnish *heat* (an ample supply of that force being afforded by the body of the parent), it seems not unlikely that its purpose is to supply a force that concurs with the heat received from without in maintaining the process of organization

16. The development of the embryo within the body, in the Mammalia, imparts to it a steady temperature equivalent to that of the parent itself; and in all, save the *implacental* Orders of this class, that development is carried still further than in Birds, the new-born Mammal being yet more complete in all its parts, and its size bearing a larger proportion to that of its parent than even in Birds. It is doubtless owing in great part to the constancy of the temperature to which the embryo is subjected that its rate of development (as shown by the fixed term of utero-gestation) is so uniform. The supply of organizable material here afforded by the ovum itself is very small, and suffices only for the very earliest stage of the constructive process; but a special provision is

* In the Viper the eggs are usually retained within the oviduct until they are hatched. In a Python, which went through the process of incubation in the Zoological Gardens, the eggs were embedded in the coils of the body; the temperature to which they were subjected)as ascertained by a thermometer placed in the midst of them) averaging 90° F., whilst that of the cage averaged 60° F.

very soon made for the nutrition of the embryo by materials directly supplied by the parent; and the imbibition of these takes the place, during the whole remainder of fœtal life, of the appropriation of the materials supplied in the Bird's egg by the 'food yolk' and 'albumen.' To what extent a retrograde metamorphosis of nutrient material takes place in the fœtal Mammal we have no precise means of determining, since the products of that metamorphosis are probably for the most part returned (through the placental circulation) to the blood of the mother, and got rid of through her excretory apparatus. But sufficient evidence of such a metamorphosis is afforded by the presence of urea in the amniotic fluid, and of biliary matter in the intestines, to make it probable that it takes place not less actively (to say the least) in the fœtal Mammal than it does in the Chick in *ovo*. Indeed, it is impossible to conceive of the growth of any of the higher organisms—which not merely consists in the formation of new parts, but also involves a vast amount of interstitial change—without perceiving that in the remodelling which is incessantly going on the parts first formed must be removed to make way for those which have to take their place. And such removal can scarcely be accomplished without a retrograde metamorphosis which, as in the numerous cases already referred to, may be considered, with great probability, as setting free constructive force to be applied in the production of new tissue.

17. If, now, we pass on from the intra-uterine life of the Mammalian organism to that period of its existence which intervenes between birth and maturity, we see that a temporary provision is made in the acts of lactation and nursing for affording both food and warmth to the young creature, which is at first incapable of adequately providing itself with aliment, or of resisting external cold, without fostering aid. And we notice that the offspring of Man remains longer dependent upon parental care than that of any other Mammal, in accordance with the higher grade of development to be ultimately attained. But when the period of infancy has passed, the child that is adequately supplied with food, and is protected by the clothing which makes up for the deficiency of other tegumentary covering, ought to be able to maintain its own heat, save in an extremely depressed temperature; and this it does by the metamorphosis of organic substances, partly derived from its own fabric, and partly supplied directly by the food into binary compounds. During the whole period of growth and development we find the producing power at its highest point; the circulation of blood being more rapid, and the amount of carbonic gas generated and thrown off being much greater in proportion to the bulk of the body than at any subsequent period of life. We find, too, in the large amount of other excretions the evidence of a rapid metamorphosis of tissue; and it can hardly be questioned (if our general doctrines be well founded) that the constructive force which operates in the completion of the fabric will be derived in part from the heat so largely generated by chemical change, and in part from the descent which a portion of the fabric itself is continually making from the higher plane of organized tissue to the lower plane of dead matter. This high measure of vital activity can only be sustained by an ample supply of Food; which thus supplies both *material* for the construction of the organism, and the *force* by whose agency that construction is accomplished. How completely dependent the constructive or organizing process still is upon Heat is shown by the phenomena of reparation in cold-blooded animals; since not only can the rate at which they take place be experimentally shown to bear a direct relation to the temperature to which these animals are subjected, but it has been ascertained that any extraordinary act of reparation (such as the reproduction of a limb in the Salamander) will

only be performed under the influence of a temperature much higher than that required for the maintenance of the ordinary vital activity.

18. After the maturity of the Organism has been attained there is no longer any call for a larger measure of constructive force than is required for the *maintenance* of its integrity; and if there were no other source of retrograde metamorphosis than that which is inherent in the peculiar composition of the tissues, the demand for food would be reduced to very little more than would suffice, by its ultimate conversion into water and carbonic acid, to keep up the Temperature of the body. But the conditions of Animal existence involve a constant expenditure of *Motor* force through the instrumentality of the Nervo-muscular apparatus as well as a liberation of Heat; and the exercise of the purely *Psychical* powers through the instrumentality of the Brain constitutes a further expenditure of force, even when no bodily exertion is made as its result.—We have now to consider the conditions under which these forces are developed, and the sources from which they are derived.

19. That the Motor force which is put forth in the contraction of a Muscle is generated by the oxygenation of the component elements, either of the muscle itself, or of the blood which circulates through it, may be considered as demonstrated by these two facts—(1) that while the blood which circulates through a Muscle at rest is returned by its veins in an almost arterial condition, its hue changes to venous as soon as the muscle is thrown into action; and (2) that the quantity of carbonic acid exhaled bears a constant relation, *ceteris paribus*, to the amount of muscular exertion put forth, as has been especially shown by the experiments of Mr. Newport and Dr. Edward Smith —the former upon Insects, the latter on the Human subject. It is interesting to note the different ways in which this oxygenation is brought about in the two cases. In the Insect, the aëration is quite independent of the blood circulation; being provided for by the direct penetration of air, through the ramifications of the *tracheæ*, into the substance of the muscles. But in Man, as in Vertebrata generally, the Blood is not only the *nutrient*, but is also the *oxygenating* medium; and, while in the organic compounds with which it is charged it has a store of "potential energy," it is only by the presence of the free Oxygen which it carries with it that those changes can be maintained whereby "potential energy" is converted into "actual energy." When the doctrine now known as that of the "Conservation of Energy"* was first worked out in regard to the production of Animal Force, it was supposed that every exertion of muscular power involved a metamorphosis of the tissue of the muscle itself sufficient in its amount to produce the mechanical equivalent of the heat that would be otherwise liberated by the combustion of its Hydrocarbon. But the observations of MM. Fick and Wislicenus on the increase of the urea, and other nitrogenous products of the disintegration of muscle, which shows itself in the urine during and after prolonged muscular exertion

* The earliest distinct general expression of this doctrine is to be found in the very remarkable treatise of Dr. Mayer ("Die organische Bewegung in ihren Zusammenhange mit dem Stoffwechsel," *Heilbronn*, 1845), in which he worked-out from the two fundamental axioms, "*Ex nihilo nil fit*," and "*Nil fit ad nihilum*," the whole system of doctrine which has since come to be known as that of the "Correlation of Forces," and the "Conservation of Energy," in its application alike to Physics and Chemistry and to Physiology. Sir William Grove was simultaneously engaged in the development of the doctrine of the "Correlation of the Physical Forces" as Prof. Helmholtz was in that of the "Conservation of Energy;" and without any knowledge of the previous labours either of Dr. Mayer or of Prof. Helmholtz, the Author of this Treatise developed a similar doctrine in his Memoir 'On the Mutual Relations of the Vital and Physical Forces,' published in the "Philosophical Transactions" for 1850.

—confirmed, as they have been, by the results of many similar inquiries—seem to place it beyond doubt that the amount of Motor energy put forth is so completely out of proportion to that of the muscular tissue which we can suppose to have been consumed, that we cannot do otherwise than attribute it in great part to the oxygenization of the non-azotized components of the Blood during its passage through the muscle. What is the peculiar condition which determines this oxidation is at present undetermined; but it would seem not improbably related to the electric changes of which (as will be shown hereafter) the contracting muscle is the seat.

20. The case seems different, however, in regard to the generation of Nerve-force; for there is great reason to believe that its production is mainly, if not entirely, dependent upon the oxygenation of the Nerve-substance itself. Its rapid metamorphosis, particularly in the cortical substance of the brain, is indicated alike by many histological characters. and by the appearance of the special products of that metamorphosis in the Urine; where the quantity of the alkaline phosphates, whose production may fairly be attributed to the oxidation of the phosphorized fats of the nerve-tissue, bears a very close relation to the quantity of Brain-work executed. The enormous supply of Blood which the Brain receives,—as much as *one-fifth* part of the whole Arterial stream being sent to an organ whose weight does not exceed *one-fortieth* that of the entire body,—is another evidence of the activity of the changes continually in progress between the Blood and the Nerve-substance. We may roughly liken the Brain to a Galvanic battery, and the Blood to its exciting liquid. When the circuit is closed, a rapid oxygenation of the Nerve-substance, as of the zinc of the battery, takes place; and a corresponding equivalent of Nerve-force (which seems closely related to, but not identical with, Electricity) is generated. But the Blood also serves for the nutritive renewal of the Nerve-substance in its intervals of repose; thus supplying it with the "potential energy," which is converted into "actual energy" by the oxygenation that destroys it as a living tissue.—How intimate is the dependence of the generation of Nerve-force on the supply of Blood to the Brain, is proved by the effect of its suspension; for if this be complete, there is an immediate cessation of consciousness and motor power. And that this cessation of activity is due rather to the want of the Oxygen supplied by the Blood, than to that of its nutrient material, appears from the experiments of Professor Bert, of the Collége de France. For having, by means of an apparatus capable of including the entire human body, and of being exhausted of its air to any required degree, brought on the faintness and exhaustion—proceeding even to a state resembling asphyxia—which is known as the *mal des montagnes*, he found that this was immediately and completely relieved by the inspiration of air highly charged with oxygen. And two aëronauts, MM. Crocé-Spinelli and Sivel, having inspired from bags containing such a mixture, found themselves in possession of their consciousness and power of exertion, under a diminution of pressure which had reduced Messrs. Glaisher and Coxwell to a state of insensibility.*

21. To sum up:—The Life of Man essentially consists in the manifestation of Forces of various kinds, of which his Organism is the instrument; and these Forces are developed by the retrograde metamorphosis of the Organic Compounds generated by the instrumentality of the Plant, whereby they ultimately return to the simple binary forms (water, carbonic acid, and ammonia), which serve as the food of plants. Of these organic Compounds,

* "Comptes Rendus," March 30, 1874.

one portion (*a*) is converted into the tissues of the living body, by a constructive force which (in so far as it is not supplied by the direct agency of external Heat) is developed by the retrograde metamorphosis of another portion (*b*) of the food. And whilst the ultimate descent of the first-named portion (*a*) to the simple condition from which it was originally drawn, becomes one source of the peculiarly Animal powers—the *psychical* and the *motor*—exerted by the organism, another source of these may be found in a like metamorphosis of a further portion (*c*) of the food which has never been converted into living tissue. The generative force, as in the Plant, is evidently an expression of the ordinary constructive force; and there seems reason, moreover, for regarding it as a very high expression, its too rapid expenditure producing a peculiarly depressing effect upon the vital power of the organism, which tends to its dissolution.—But whilst we find the ultimate source of the whole vital power of the organism in the supplies of Food and of Heat which it derives from external sources, it must never be forgotten that its capacity to avail itself of those supplies depends upon its own original constitution; and that as the form into which the Germ develops itself depends upon its own *specific* endowments, so the particular modification of that form presented by each individual must depend (all external conditions being the same) upon its own *individual* endowments—the differences between these being at present only vaguely referable to antecedent conditions of the parental organism.

CHAPTER II.

DISTINCTIVE CHARACTERISTICS OF MAN.

22. In entering upon the study of that aggregation of phenomena which constitutes the Life of Man, it seems appropriate in the first instance to consider his relations to other types of Animal organization; and to examine what there is in his corporeal and psychical characters, which most distinctly differentiates him from the beings he most nearly resembles. All Zoologists are agreed that his place is at the head of the Mammalian class of the Vertebrate sub-kingdom; and that as regards both the general plan of conformation and the details of anatomical structure, there is a very close approximation between the genus *Homo* and the semi-erect tail-less Apes belonging to the genera *Troglodytes* and *Pithecus*. But there is a considerable difference of opinion as to the mode in which this relationship should be expressed. By Linnæus, the Apes and Man were included with Lemurs and Bats in one and the same Order Primates; and in this non-separation of Man from the Apes, he has been followed by several modern Zoologists of great eminence. On the other hand, Blumenbach, who in this was followed by Cuvier, maintained that the distinctive characters of the genus *Homo* are sufficient to entitle man to rank as the type of a separate Order, to which he gave the name of Bimana, considering it to be specially distinguished by the possession of two hands from the Quadrumana, which possess four nearly similar hand-like extremities. And Prof. Owen has recently gone a step further, by raising *Homo* into a sub-class Archencephala, on the ground that his "psychological powers, in association with his extraordinarily developed brain, entitle the group which he represents to equivalent rank with the

other primary divisions of the class Mammalia, founded on cerebral characters."* Although the discussion of questions of systematic arrangement is the proper business of the Zoologist, yet the inquiry into the exact nature and amount of the differences between *Man* and the (so-called) *Quadrumana* falls legitimately within the province of the Physiologist, and may therefore be appropriately dealt with in this place. In the pursuit of this inquiry, it is most important to distinguish between those structural peculiarities of which alone the Anatomist can take cognizance, and those psychical manifestations of which the sources are altogether beyond his ken; for these two orders of facts cannot be legitimately brought into the same category, and any attempts to blend them can lead to nothing but confusion. It is the province of the Comparative Anatomist to deal with Man's corporeal organism, as if he knew nothing more than the facts brought under his observation in the dissecting-room; scrutinizing every peculiarity in its structure in exactly the same spirit, and valuing it according to exactly the same measure, that he would bring to the investigation of the peculiarities of some newly-discovered type, known to him only by dead specimens. And although he might safely assign to the genus *Homo* a structural capacity for the erect posture,—a speciality in the conformation of the anterior and posterior extremities, imparting to the former a peculiar power of varied and minute prehension, and fitting the latter for biped progression,—and a relatively-larger and more complex brain, rendering it probable that the psychical faculties of which it is the instrument would be more elevated and more predominant,—yet there he must stop; since he cannot discover in Man's corporeity the faintest indication of those Intellectual and Moral attributes by which he holds himself to be specially distinguished from the brute creation, of that Progressive Reason which draws even the Infinite within its scope, of that upward aspiration after Truth and Goodness which ranges even beyond his intellectual conception, of that yearning after a purely Spiritual existence which refuses to recognise in bodily decay anything but the liberation of the imprisoned Soul. These are facts of Man's nature not less necessary to be taken into account in the estimation of his position in the Universe than those which are supplied by his bodily organization; and it is not surprising that by a too exclusive regard to them, many eminent Naturalists, from Aristotle downwards, have been led to maintain that Man ought not to be included in the Animal Kingdom at all, but should be ranked in a Kingdom by himself. This, however, is a position which cannot be consistently held by any one who recognises Anatomical structure as the true basis of Zoological classification. For granting that Man is distinguished from every other form of terrestrial being by psychical attributes which bring him into relation with Infinite Intelligence, he does not the less belong to the Animal Kingdom in his present stage of existence, in virtue of his possession of every attribute by which an Animal is characterized, and the absence of any peculiarity whatever in his organization which can be shown to remove him from that category. And since it is only *as an animal* that he is taken cognizance of by the Zoologist, it is only with his structural characters that the Zoologist should concern himself. In this point of view it appears to the author clearly demonstrable that the structural distinctions by which Man is separated from the higher Apes are much smaller in amount than those by which the latter are separated from the lower Quadrumana; and hence that the Linnæan association of *Man*

* 'On the Characters and Classification of the Mammalia,' in "Journal of the Proceedings of the Linnæan Society," vol. ii. 1857, p. 33.

and the *Quadrumana* in the same primary group is much more correct than the ordinal separation of the *Bimana* and *Quadrumana* maintained by Cuvier, and *à fortiori* than the proposition of Prof. Owen to rank Man in a distinct sub-class.

23. As the ordinal separation of the *Bimana* from the *Quadrumana* has come to be generally accepted upon the authority of Cuvier, it will be desirable to begin by examining into the validity of the characters on which it rests; comparing, in the first place, the hand and the foot of Man with the corresponding extremities of the higher Apes; and then inquiring whether the differences which they respectively present, either surpass in *degree* those with which we meet in a like comparison between the extremities of the higher Apes and those of the lower Monkeys, or can be justly held to depart from them in *kind*. There is in Man, what we observe in none of the Mammalia which approach him in other respects, a complete distinction in the character of the anterior and posterior extremities; the former being adapted for prehension alone, and the latter almost exclusively for support and progression: and thus each function is performed with much greater completeness, than it can be when two such opposite purposes have to be united. "That," says Cuvier, "which constitutes the *hand*, properly so called, is the faculty of opposing the thumb to the other fingers, so as to seize upon the most minute objects; a faculty which is carried to its highest degree of perfection in Man, in whom the whole anterior extremity is free, and can be employed in pre-

Fig. 1.

Hand of *Man*, compared with anterior extremity of *Orang*.

hension." The peculiar prehensile power possessed by the *Hand* of Man is chiefly dependent upon the size and power of the thumb; which is more developed in him, than it is in the highest Apes (Fig. 1). The thumb of the Human hand can be brought into exact opposition to the extremities of all the fingers, whether singly or in combination; while in those Quadrumana which most nearly approach Man, the thumb is so short, and the fingers so much elongated, that their tips can scarcely be brought into opposition; and the thumb and fingers are so weak, that they can never be opposed to each other with any degree of force. Hence, although well suited to cling round bodies of a certain size, such as the small branches of trees, &c., the anterior extremities of the Quadrumana can neither seize very minute objects with such precision, nor support large ones with such firmness, as are essential to

the dexterous performance of a variety of operations for which the hand of Man is admirably adapted. This adaptation, however, is not obtained by means of any new instrumentality; for the anterior extremity of the Orang or Chimpanzee possesses not only every bone, but every muscle, which is found in that of Man; and its only structural differences consist in the proportionate development of the several components of these organs respectively.—But the functional powers of the anterior extremity are not related solely to its own structure; since the use that can be made of the limb depends in part upon its relations to the body at large, the general conformation of which must be adapted to turn its special capacity to advantageous account. Thus, while the arm of the higher Apes has as wide a range of motion as that of Man, so far as its articulation is concerned, it is only when the animal is in the erect attitude that the limb can have free play. And even the most perfect organization of the hand as an instrumental structure would be comparatively valueless, without the *mind* by which its actions are prompted, and the *senses* by which they are guided.

24. The *Foot* of Man, in like manner, differs from that of the higher Apes, in those characters which specially adapt it to the support of the body in the erect posture, and to biped progression; in which adaptation it loses much of that prehensile power which the posterior extremities of the higher Quadrumana possess almost equally with their anterior. The Human foot is, in proportion to the size of the whole body, larger, broader, and stronger, than that of any other Mammal save the Kangaroo. The surface of the Astragalus, which articulates with the tibia, looks almost vertically upwards, and hardly at all inwards when the sole is flat upon the ground, and the lateral facets are more nearly at right angles to this surface than in any Ape. The plane of the foot is directed at right angles to that of the leg; and its sole is concave, so that the weight of the body falls on the summit of an arch, of which the os calcis and the metatarsal bones form the two points of support. This arched form of the foot, and the contact of the whole plantar surface with the ground,

Fig. 2.

Foot of *Man*, compared with posterior extremity of *Orang*.

are peculiarly noticeable in Man; most of the Apes having the os calcis small, straight, and more or less raised from the ground, which they touch, when standing erect, with the outer side only of the foot (Fig. 2). The function of the *hallux*, or great-toe, moreover, is strikingly contrasted in Man and the

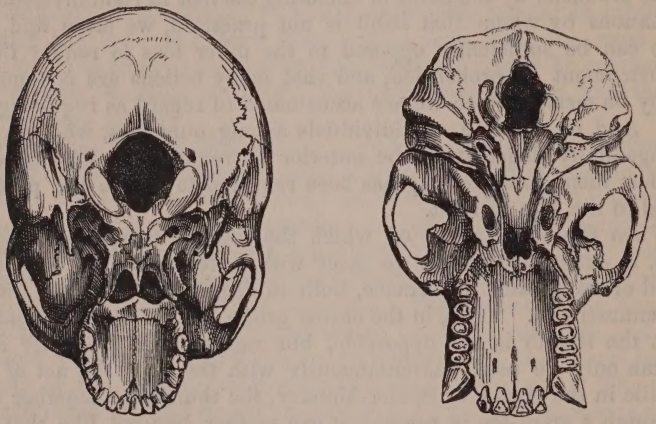
Apes; for whilst in the latter it is nearly as opposable as the thumb, and can be used to almost the same degree as an instrument of prehension, it chiefly serves in the former to extend the basis of support, and to advance the body in progression. But neither in its osteology nor in its myology is there any essential difference between the foot of Man and the posterior extremity of the higher Apes; for every bone and every muscle in the one has its counterpart in the other; and there is nothing which really assimilates the posterior to the anterior extremity of the Ape, or entitles the former to be considered as a hand, save the opposability of the great-toe. It is certain, moreover, that this faculty is not originally wanting in Man, although it may be destroyed by the disuse produced by the habit of enclosing the foot in rigid investments; for among nations by whom that habit is not practised, we often find that the great-toe can be sufficiently opposed to the other toes to render the foot a useful instrument of prehension, and that many actions are commonly performed by its means, which we are accustomed to regard as requiring *manual* agency. And in the case of individuals among ourselves, who have either been congenitally deficient in the anterior extremities, or who have subsequently lost them, practice only has been required to enable the posterior to be turned to the like account.

25. When the comparison, of which the leading points have now been sketched, is extended further, we meet with differences that cannot but be accounted of far greater importance, both in degree and in kind, than those already enumerated. Thus, in the entire group of *Platyrrhine* Monkeys, we find that the thumb is not opposable, but ranges with the other digits, so that it can only be used consentaneously with them in the act of prehension; while in the *Ateles*, or Spider-Monkey, the thumb is altogether wanting, and although a great-toe is present, it can neither be used like that of Man for support, nor be opposed to the other digits as in the higher Quadrumana, the posterior and anterior extremities being strikingly assimilated in structure, and being alike adapted to serve only as *claspers*. Among the Baboons and Lemurs, moreover, we find that the conformation alike of the anterior and of the posterior extremities is such as to assimilate them at least as much to the lower *quadrupedal* as to the higher *quadrumanous* type; so that between the two extremes of the series of which the anthropoid Apes are the highest and the Baboons and Lemurs are the lowest members, there is a far wider interval, as regards the conformation of the extremities, than that which separates the former from Man.

26. The next series of distinctive characters to be considered, are those by which Man is adapted to the erect attitude.—On examining his *Cranium*, we remark that the occipital condyles are so placed, that a perpendicular dropped from the centre of gravity of the head would nearly fall between them, so as to be within the base on which it rests upon the spinal column. The foramen magnum is not placed in the centre of the base of the skull, but just behind it; so that the greater specific gravity of the posterior part of the head, which is entirely filled with solid matter, is compensated by the greater length of the anterior part, which contains many cavities. There is, indeed, a little over-compensation, which gives a slight preponderance to the front of the head, so that it drops forwards and downwards when all the muscles are relaxed; but the muscles attached to the back of the head are far larger and more numerous than those in front of the condyles, so that they are evidently intended to counteract this disposition; and we accordingly find ourselves able to keep up the head for the whole day with so slight and involuntary an effort that no fatigue is produced by it. Moreover, the

plane of the foramen magnum and the surfaces of the condyles have a nearly horizontal direction when the head is upright; and thus the weight of the skull is laid vertically upon the top of the vertebral column.—If these arrangements be compared with those which prevail in other Mammalia, it will be found that the foramen and condyles are placed in the latter much nearer the back of the head, and that their plane is more oblique. Thus, whilst the foramen magnum is situated in Man just behind the centre of the base of the skull, it is found in the Chimpanzee and Orang Outan to occupy the middle of the posterior third (Fig. 3); and, as we descend through the scale of

Fig. 3.



View of the base of the Skull of *Man*, compared with that of the *Orang Outan*.

Mammalia, we observe that it gradually approaches the *back* of the skull, and at last comes nearly into the line of its longest diameter, as we see in the Horse. Again, in all Mammalia except Man, the plane of the condyles is oblique, so that, even if the head were equally balanced upon them, the force of gravity would tend to carry it forwards and downwards; in Man, the angle which they make with the horizon is very small; in the Orang Outan, it is as much as 37°; and in the Horse, their plane is vertical, making the angle 90°. If, therefore, the natural posture of man were horizontal, the plane of his condyles would be brought, like that of the Horse, into the vertical position; and the head, instead of being nearly balanced on the summit of the vertebral column, would hang at the end of the neck, so that its whole weight would have to be supported by some external and constantly-acting power. But for this, there is neither in the skeleton, the ligamentous apparatus, nor the muscular system of Man, any adequate provision; so that in any other than the vertical position, his head, which is relatively heavier than that of most Mammalia, would be supported with more difficulty and effort than it is in any other animal.

27. The position of the *Face* immediately beneath the brain, so that its front is nearly in the same plane as the forehead, is peculiarly characteristic of Man; for in the skulls of the Chimpanzee and Orang, which approach nearest to that of man, the cranial portions are rather posterior to, than above, the facial (Figs. 4, 7). The projection of the muzzle, taken in connexion with the obliquity of the condyles, is another evidence of want of perfect adaptation to the erect posture; whilst the absence of prominence in the face of Man shows that none but the erect position can be natural to him. For supposing

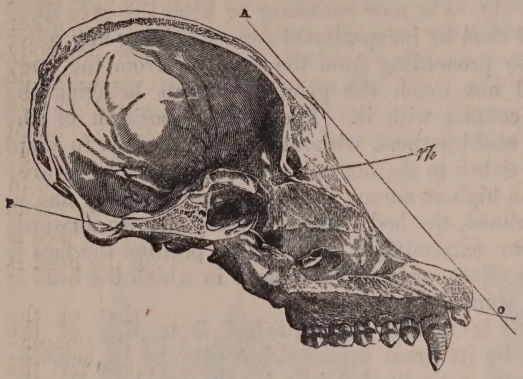
that, with a head formed and situated as at present, he were to move on all-fours, his face would be brought into a plane parallel with the ground; so that as painful an effort would be required to examine with the eyes an object placed in front of the body, as is now necessary to keep the eyes fixed on the zenith; the nose would then be incapacitated from receiving any other odorous emanations than those proceeding from the earth or from the body itself; and the mouth could not touch the ground without bringing the forehead and chin also into contact with it. The oblique position of the condyles in the Quadrumana enables them, without much difficulty, to adapt the inclination of their heads either to the horizontal or to the erect posture; but the natural position, in the highest among them, is unquestionably one in which the spinal column is inclined, the body being partially thrown forwards so as to rest upon the anterior extremities; and in this position the face is directed forwards without any effort, owing to the mode in which the head is obliquely articulated with the spine (Fig. 7).

28. The Cranium of Man is further distinguished from that of the anthropoid Apes, not merely by its great capacity, but also by its smoothness; its surface being almost entirely deficient in those ridges for the attachment of muscles, which are remarkably strong in both the Chimpanzee and the Orang, and which impart to its configuration somewhat of a carnivorous aspect. This aspect is strengthened by the great depth of the temporal fossa, and by the extent and strength of the zygomatic arch; features that are most remarkably developed in the *Troglodytes gorilla* (Fig. 7). The breadth of the upper part of the face is a noticeable feature in Man; the eyes being set widely apart, and the interorbital space occupying one-fourth of the interval between the outer walls of the orbits.* The inner walls of the orbits formed by the ossa plana of the ethmoid are nearly parallel to one another. Moreover, the jaws in even the most degraded races of Man project far less from the general plane of the face than they do in the Apes; and his teeth are arranged in a continuous series, without any hiatus or any considerable difference in length; whilst all the Apes, in their adult state at least, are furnished with canine teeth of extraordinary length, between the sockets of which and those of the adjoining teeth (anteriorly in the upper jaw, and posteriorly in the lower) there is a vacant space or 'diastema.' Even in the most prognathous Human skulls, moreover, the incisors meet each other much more nearly in the same axis than they do in the anthropoid Apes, in which they form an angle with each other that is not nearly so divergent. The fusion of the intermaxillary or premaxillary bones with the superior maxillary, at an early period of fœtal life, is a remarkable character of the Human cranium, as distinguishing it from that of the Apes, in which the intermaxillary bones remain separate to a much later period, sometimes differing also very considerably both in size and shape. Thus, in the *Troglodytes gorilla*, these bones are not only remarkable for their prominence, but also for their upward extension round the nostrils, so that they completely exclude the maxillary bones from their borders, and from the basis of support for the nasal bones; and although they coalesce with the maxillaries at and near the alveolar portion, they remain separate elsewhere. The lower jaw of Man is remarkable for that prominence at its symphysis which forms the chin; and although this, also, is least developed in the most prognathous Human crania, yet it is never so deficient as it is in the lower jaw of the Chimpanzee and

* Huxley's "Anatomy of the Vertebrate Animals," 1871, p. 489.

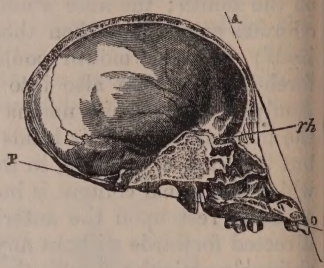
Orang.—It is curious to observe that the skulls of the *young* of Man and of the anthropoid Apes resemble one another much more than do those of the

Fig. 4.



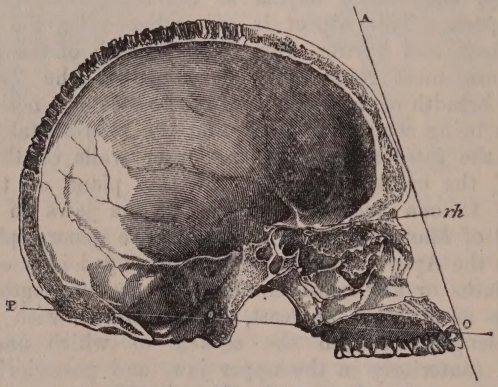
Vertical section of Skull of *Adult Orang.*

Fig. 5.



Vertical section of Skull of *Young Orang.*

Fig. 6.



Vertical section of Skull of *Papuan Negrito.*

adults; each tending to diverge, in its advance towards full development, from a type which seemed almost similar in both (Figs. 4, 5, 6). It is at the time of the second dentition that the muzzle of the anthropoid Apes acquires its peculiar elongation and consequent projection in front of the forehead (Figs. 5, 4); and the whole cast of the features is altered at the same time, so that it approaches much more to that of the lower Quadrumana than would be supposed from observation of the young animal only.* In the Human subject, on the other hand, we see that, although in the advance from childhood to adult age, there is a progressive enlargement of the face in proportion to the capacity of the cranial cavity, this augmentation is comparatively small in amount, and but little affects the general configuration of the cranium.†

29. The great size of the *cranial* portion of the skull in Man, as compared

* None but young specimens of the Chimpanzee and Orang Outan have ever been brought alive to this country; and they have never long survived the period of their second dentition.

† See Prof. Owen's Papers on the Anatomy of the Orang and Chimpanzee, in the "Zoological Transactions," vols. i. and iii.; and Prof. Vrolik in the Art. *Quadrumana* in the "Cyclopædia of Anatomy and Physiology," vol. iv.

with the *facial*, produces a marked difference between his 'facial angle' and that of even the highest Quadrumana. According to Camper, who first applied this method of measurement, the 'facial angle' of the average of European skulls is 80°, whilst in the ideal heads of the Grecian gods it is increased to 90°; on the other hand, in the skull of a Kalmuck he found it to be 75°, and in that of a Negro only 70°; and applying the same system of measurement to the skulls of Apes he found them to range from 64° to 60°. But these last measurements were all taken from young skulls, in which the forward extension of the jaws, which takes place on the second dentition, had not yet occurred. In the adult Chimpanzee, as Prof. Owen has shown, the 'facial angle' (Figs. 4, 5, 6, A O P) is no more than 35°, and in the adult Orang only 30°; so that instead of the Negro being nearer to the Ape than to the European, as Camper's estimate would make him, the interval between the most degraded Human races and the most elevated Quadrumana is considerably greater than between the highest and the lowest forms of Humanity. It must be borne in mind, however, that the 'facial angle' is so much affected by the degree of prominence of the jaws that it can never afford any certain information concerning the elevation of the forehead and the capacity of the cranium; all that it can in any degree serve to indicate, being the relative proportion between the facial and the cranial parts of the skull. This proportion is far more correctly determined, as Prof. Owen has shown,* by vertical sections of the skulls to be compared, through their median planes (Figs. 4, 5, 6); and from an extended comparison of such sections, it appears that whilst the difference between the cranial cavity of the higher Apes and that of Man is rather one of relative size than of conformation, there is a far more strongly-marked difference, not only in relative size but also in conformation, between the cranial cavities of the higher and those of the lower Quadrumana, the latter being not only far less capacious in proportion to the size of the body, but being also disposed in such a manner that its long diameter comes to be continuous (as in Quadrupeds generally) with the axis of the spinal canal, instead of crossing it nearly at right angles as in Man. The length of the cerebral cavity in Man is more than twice that of the basi-cranial axis. Its capacity in the healthy adult is invariably more than forty cubic inches, and may rise to more than a hundred cubic inches (Huxley).

30. The *Vertebral Column* in Man, although not absolutely straight, has its curves so arranged that, when the body is in an erect posture, a vertical line from its summit would fall exactly on the centre of its base. It increases considerably in size in the lumbar region, so as altogether to be somewhat pyramidal in form. The lumbar portion in the Chimpanzee and Orang is not of the same proportional strength, and contains but four vertebræ instead of five. The processes for the attachment of the dorso-spinal muscles to this part are peculiarly large and strong in Man; and this arrangement is obviously adapted to overcome the tendency which the weight of the viscera in front of the column would have to draw it forwards and downwards. On the other hand, the spinous processes of the cervical and dorsal vertebræ, which in other Mammalia are large and strong for the attachment of the ligaments and muscles that support the head, and which are peculiarly pronounced in the Gorilla (Fig. 7), have comparatively little prominence in Man, his head being nearly balanced on the top of the column.—The base of the Human vertebral column is

* "Zoological Transactions," vol. iv. p. 77 *et seq.*

placed on a sacrum of greater proportional breadth than that of any other animal; this sacrum is fixed between two widely-expanded ilia; and the whole *pelvis* is thus peculiarly broad. In this manner, the femoral articulations are thrown very far apart, so as to give a wide basis of support; and by the oblique direction of the pelvis, the weight of the body is transmitted almost vertically from the top of the sacrum to the upper part of the thigh bones. The pelvis of the anthropoid Apes is very differently constructed; as will be seen in the adjoining PLATE, in which the skeleton of the Orang is placed in proximity with that of Man. It is much larger and narrower; its alæ extend upwards rather than outwards, so that the space between the lowest ribs and the crest of the iliac bones is much less than in Man; their surfaces are nearly parallel to that of the sacrum, which is itself longer and narrower; and the axis of the pelvis is nearly parallel with that of the vertebral column. The position of the Human femur in which its head is most securely retained in its deep acetabulum is that which it has when supporting the body in the erect attitude; in the Chimpanzee and Orang its analogous position is at an oblique angle to the long axis of the pelvis, so that the body leans forwards in front of it (Fig. 7); in many Mammalia, as in the Elephant, it forms nearly a right angle with the vertebral column; and in several others, as the Horse, Ox, &c., the angle which it makes with the axis of the pelvis and vertebral column is acute. In these respects, then, the skeleton of Man presents an adaptation to the erect posture, which is exhibited by that of no other Mammal; but that of the anthropoid Apes presents a far nearer approximation to the Human model in all the foregoing particulars, than it does to that of the lower Quadrumana.

31. There is a considerable difference in the form of the *trunk* between Man and most other Mammalia; for his thorax is expanded laterally, and flattened in front, so as to prevent the centre of gravity from being carried too far forwards; and his sternum is short and broad. Between the bony walls of the thorax and the margin of the pelvis a considerable space intervenes, which is occupied solely by muscles and tegumentary membranes; and these would be quite insufficient to sustain the weight of the viscera, if the habitual position of the trunk had been horizontal.—In these particulars, however, the most anthropoid Apes agree more or less completely with Man.

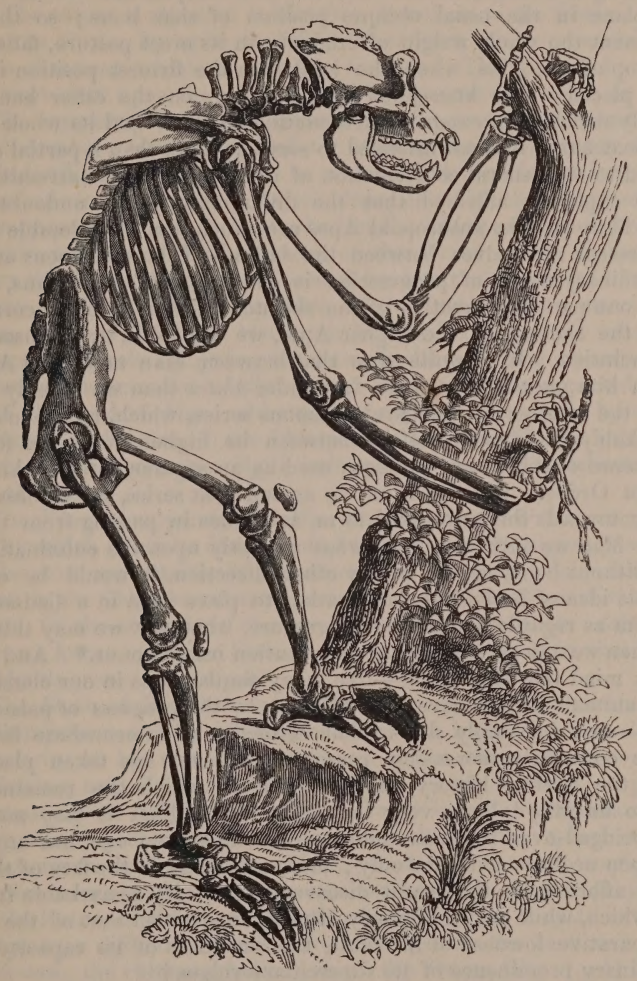
32. The *lower extremities* of Man are remarkable for their relative length, which is greater than that which we find in any other Mammalia, except the Kangaroo tribe. The chief difference in their proportions between Man and the semi-erect Apes is seen in the thigh; and it is from the relative length of this part in him that the middle point of the height of the body is in the adult as low as the symphysis pubis, and further from the comparative shortness of his anterior extremities, his hands only reach the middle of his thighs, whilst in the Chimpanzee they hang on a level with the knees (Fig. 7), and in the Orang they descend to the ankles (PLATE).* The Human femur is

* The following Table (Beaunis, "Nouveaux Éléments de Physiologie Humain," p. 40) gives the lengths of the limbs as compared with the vertebral column in Man and the higher Apes:—

	European.	Bushman.	Gorilla.	Chimpanzee.	Orang.
Vertebral column	100	100	100	100	100
Arm	80	78	115	96	122
Leg	117	110	96	90	89
Hand	26	26	36	43	48
Foot	35	32	41	39	52

distinguished, however, by its form and position, as well as by its length. The obliquity and length of its neck still further increase the breadth of the

Fig. 7.



Skeleton of *Troglodytes Gorilla.*

hips; whilst they cause the lower extremities of the femora to be somewhat obliquely directed towards each other, so that the knees are brought more into the line of the axis of the body. This arrangement is obviously of great use in facilitating the purely *biped* progression of Man, in which the entire weight of the body has to be alternately supported on each limb; for if the knees had been kept further apart, the whole body must have been swung from side to side at each step, so as to bring the centre of gravity over the top of each tibia; as is seen to a certain extent in the female sex, whose walk, owing to the greater breadth of the pelvis and the separation between the knees, is less steady than that of the male. There is also a marked difference

between the knee-joint of Man and that of even the highest Apes. In the former, the opposed extremities of the femur and the tibia are so expanded as to present a very broad articulating surface, and the internal condyle of the femur being the longer of the two, the two condyles are in the same horizontal plane in the usual oblique position of that bone; so that by this arrangement the whole weight of the body, in its erect posture, falls vertically on the top of the tibia, when the joint is in the firmest position in which it can be placed. The knee-joint of the Orang, on the other hand, is comparatively deficient in extent of articulating surface; and its whole conformation indicates that it is not intended to serve as more than a partial support.—In regard to the general conformation of the bones of the extremities, it may be most explicitly affirmed that the differences which undoubtedly exist between Man and the anthropoid Apes are much less considerable than those which present themselves between the latter and those Baboons and Lemurs whose ordinary mode of progression is *quadrupedal*. And thus, after contrasting one part after another of the skeleton of Man with the corresponding parts of the skeleton of the higher Apes, we are led in every instance to the same conclusion. It is quite true that between Man and those Apes which approach him most closely there is a wider *hiatus* than we usually meet with between the members of the Quadrumanous series, which, as a whole, presents a remarkably gradational position between its higher and lower forms; and the existence of this *hiatus* has been used as an argument for ranking Man in a distinct Order. But since, as we ascend that series, we witness a gradual tendency towards the anthropoid form, and since in passing from the highest Apes to Man we only come somewhat abruptly upon the culmination of that ascent without being led off in any other direction, it would be contrary to the whole idea of Zoological classification to place Man in a distinct category from them as regards his corporeal structure, whatever we may think it right to do when we take his psychical constitution into account.* And it is to be borne in mind that this *hiatus*—like many similar gaps in our classification of existing animals which have been filled up by the progress of palæontological research—*may* be simply due to that extinction of intermediate forms which (there is constantly increasing reason to believe) has taken place in past ages of the Earth's history, to an extent of which the remains hitherto known to us afford but a very imperfect idea. That it *may not* be completely bridged-over by such intermediate links, no one has any right to affirm upon negative evidence only; more especially in the face of the positive evidence afforded by the recent discovery of a very remarkable fragment of a skull which, while unquestionably Human, resembled that of the Gorilla in the comparative lowness of its vault, the smallness of its capacity, and the extraordinary prominence of its superciliary ridges.†

33. The most characteristic peculiarity of the Human *Myology* is the great

* We meet with a similarly abrupt transition at the other extremity of the series, in the *Cheiromys* or Aye-aye; an animal which Zoologists now agree to rank among the Quadrumana in virtue of its general Lemurine affinities, although in dentition and several other particulars it bears so strong a resemblance to the Rodents as to have been placed among them by Cuvier.

† See "Nat. Hist. Rev.," vol. i. 1861, p. 155; and Prof. Huxley 'On some Fossil Remains of Man,' in his "Evidence as to Man's Place in Nature," 1863. The anatomical peculiarities of Man are very completely given by Prof. Huxley, in his "Anatomy of Vertebrated Animals," 1871, p. 488 *et seq.;* see also Broca, "L'ordre de Primates Bulletin de la Soc. d'Anthropol.," 1869. The student will find an admirable exposition of the structural resemblances and differences between Man and Apes in St. George Mivart's little work, entitled "Man and Apes," 1873. In this work Mr. Mivart strongly opposes the doctrine of the descent of Man and Apes from a common ancestor.

development of those muscles of the trunk and limbs which contribute to the maintenance of the erect posture. Thus, the gastrocnemii, and the other muscles which tend to keep the leg erect upon the foot, form a much more prominent 'calf' than is seen either in the most anthropoid Apes, or in any other animal. The soleus is attached to the tibia as well as to the fibula. So, again, the extensors of the leg upon the thigh are much more powerful than the flexors; a character which is peculiar to Man. The glutæi, by which the pelvis is kept erect upon the thigh, are of far greater size than is elsewhere seen. The superior power of the muscles tending to draw the head and spine backwards has been already referred-to. Among the differences in the attachment of individual muscles, it may be noticed that the 'flexor longus pollicis pedis' proceeds in Man to the great-toe alone, on which the weight of the body is often supported; whilst it is attached in the Chimpanzee and Orang to the three middle toes also. All four heads of the flexor brevis digitorum pedis arise from the Calcaneum, and the second toe has two dorsal interossei. The 'latissimus dorsi' is destitute in Man of that prolongation attached to the olecranon, which is found in the lower Mammalia, and which exists even in the Chimpanzee, probably giving assistance in its climbing operations. The larger size of the muscles of the thumb is, as might be expected, a characteristic of the hand of Man; although the number of muscles by which that digit is moved is the same in the Chimpanzee as in the Human subject. The separation of the 'extensor digiti indicis,' however, as a distinct muscle, is peculiar to Man.

34. The *Visceral* apparatus of Man presents very few characteristic peculiarities by which it can be distinguished from that of the higher Quadrumana; among the most remarkable is the absence of the laryngeal pouches, which exist even in the Chimpanzee and Orang Outan, as dilatations of the laryngeal ventricles. Of the anatomy of the last-named animals in their *adult* condition, however, we know as yet too little to enable its conformity to that of Man to be confidently pronounced upon.

35. The *Brain* of Man does not differ so much in conformation from that of the Chimpanzee, and in this respect still more highly-developed Orang, as the superiority of his mental endowments might have led us to anticipate. The following are the principal differences which it seems to present:—1. The mass of the entire brain is considerably larger in proportion to that of the body, and in proportion also to the diameter of the spinal cord, and of the nerves which are connected with it.—2. In the external configuration of the Cerebrum we notice that its *anterior* lobes are larger, project further beyond the Rhinencephalon, or Olfactive Ganglion, than they do in the highest Quadrumana; a difference which is well marked in the sectional contour of the brain-case, the rhinencephalic fossa of the Orang (Fig. 4, *rh*) being at its most anterior part; whilst even in the least elevated forms of the Human skull, this fossa (of which the cribriform plate of the ethmoid bone constitutes the floor) has no inconsiderable part of the cranial cavity in front of it (Fig. 6, *rh*). —3. The Cerebrum as a whole projects further beyond the Cerebellum than in the Quadrumana generally, which is due, not to any increase in size of the occipital Convolutions, but to the great development of the 'bridging convolutions' interposed between the parietal and occipital lobes.—4. The Convolutions are more numerous and complex, and usually more or less unsymmetrical, and the sulci are deeper. It appears, however, that in the lower races of Mankind the brain presents, both in the simplicity and the precise symmetry of its convolutions, a much closer approximation to the Quadrumanous type than it does in the higher.—5. On examining the internal struc-

ture it is found that the peripheral layer of grey matter is thicker, the corpus callosum extends further backwards, and the posterior cornua of the lateral

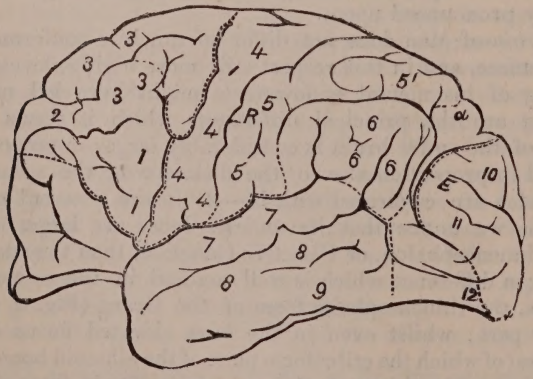
ventricles are relatively longer and larger than they usually are in Quadrumana.*—6. The Cerebellum, also, is proportionally larger. The relative

Fig. 9.



Brain of Orang (Simia). Left side.

development of the Cerebrum in Man and the three highest Apes is well shown in the accompanying drawings (Figs. 8, 9, 10).

36. The small size of the face of Man, compared with that of the cranium, is an indication that in him the *senses* are subordinate to the *intelligence*. Accordingly, we find that while he is surpassed by many of the lower animals in acuteness of sensibility to light, sound, &c., he stands pre-eminent in the

power of comparing and judging of his sensations, and of thence drawing conclusions as to their objective sources. Moreover, although none of his senses are very acute in his natural state, they are all moderately so; and

Fig. 10.

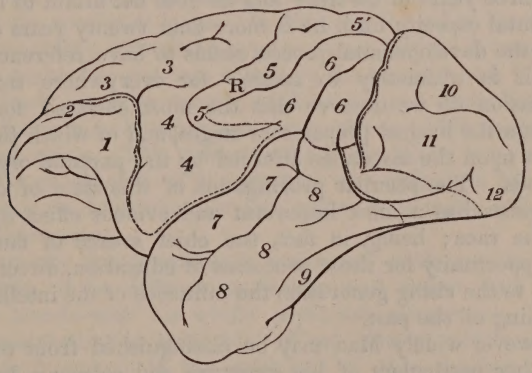
they are capable of being wonderfully improved by practice, when circumstances strongly call for their exercise. This seems especially the case with

Fig. 11.



Brain of Mandrill Baboon (Cynocephalus). Left side.

the *tactile* sense, of which Man can make greater use than any other animal, in consequence of the entire freedom of his anterior extremities; although there are many which surpass him in their power of appreciating certain classes of tactile impressions.—So, again, Man's nervo-muscular power is inferior to that of most other animals of his size: the full-grown Orang, for example, surpasses him both in strength and agility; and the Gorilla, according to the statements of the Negroes who have encountered it, is more than a match for any single man, and is almost certain to destroy any human opponent once within his grasp.—The absence of any natural weapons of offence, and of direct means of defence, are remarkable characteristics of Man, and distinguish him not only from the lower Mammalia, but also from the most anthropoid Apes; in which it is obvious (both from their habits and general organization) that the enormous canines have no relation to a carnivorous regimen, but are instruments of warfare. On those animals to

which Nature has denied weapons of attack, she has bestowed special means either of passive defence, of concealment, or of flight; in each of which Man is relatively deficient. Yet by the superiority of his reason he has been enabled not only to resist the attacks of other animals, but even to bring them into subjection to himself. His intellect can scarcely suggest the mechanism which his hands cannot frame; and he has devised and constructed arms more powerful than those which any creature wields, and defences so secure as to defy the assaults of all but his fellow-men.

37. Man is further remarkable for his extraordinary power of adaptation to varieties in external condition, which renders him to a great extent independent of them. He is capable of sustaining the highest as well as the lowest extremes of temperature and of atmospheric pressure. In the former of these particulars, he is strikingly contrasted with the anthropoid Apes; the Gorilla and Chimpanzee being restricted to the hottest parts of Africa, and the Orang Outan to the tropical portions of the Indian Archipelago; and neither of these animals being capable of living in temperate climates without the assistance of artificial heat, even with the aid of which they have not hitherto long survived their second dentition. So, again, although Man's diet seems naturally of a mixed character, he can support himself in health and strength either on an exclusively vegetable diet or an almost exclusively animal regimen.

38. The slow growth of Man, and the length of time during which he remains in a state of dependence, are peculiarities that remarkably distinguish him from all other animals. He is unable to obtain his own food during at least the first three years of his life; and he does not attain to his full bodily stature and mental capacity until he is more than twenty years of age. This retardation of the developmental process seems to have reference to the high grade which it is ultimately to attain; for everywhere throughout the Organized Creation do we observe that the most elevated forms are those which go through the longest preparatory stages, and of which the evolution is most dependent upon the assistance afforded by the parental organism during its earlier periods. The peculiar prolongation of this state of dependence in the Human species has a most important and evident effect upon the social condition of the race; being, in fact, the chief source of family ties, and affording the opportunity for those processes of education, direct and indirect, which transmit to the rising generation the influence of the intellectual culture and moral training of the past.

39. Still, however widely Man may be distinguished from other animals, by these and other particulars of his structure and economy, he is yet more distinguished by those *mental* endowments, and by the habitudes of life and action thence resulting, which must be regarded as the essential characteristics of Humanity. It is in adapting himself to the conditions of his existence, in providing himself with food, shelter, weapons of attack and defence, &c., that Man's intellectual powers are first called into active operation; but when thus aroused, their development has no assignable limit. The Will, guided by the intelligence, and acted-on by the desires and emotions, takes the place in Man of the Instinctive propensities which are usually the immediate springs of action in the lower animals; for although, among the most elevated of these, a high amount of Intelligence is exhibited, yet its operations seem to be always directly attributable to external suggestions, present or remembered; and the character never rises beyond that of the child. In fact, the correspondence between the psychical endowments of the Chimpanzee, and those of a Child of three years old who has not yet begun to speak, is very close.—One of the most important aids in the use and development of the Human

mind is the capacity for *articulate speech;* of which, so far as we know, Man is the only animal in possession. There is no doubt that many other species have certain powers of communication between individuals; but these are probably very limited, and of a kind more allied to "the language of signs" than to a proper verbal language. In fact, it is obvious that the use of a language composed of a certain number of distinct sounds, combined into words in a multitude of different modes, requires a power of intellectual abstraction and generalization, in which it appears that the lower animals are altogether deficient. So, again, verbal language affords the only means whereby abstract ideas can be communicated; and those who have perused the interesting narrative given by Dr. Howe of his successful training of Laura Bridgeman, will remember how marked was the improvement in her mental condition, from the time when she first apprehended the fact that she could give such distinct expression to her thoughts, feelings, and desires, as should secure their being comprehended by others.

40. The *capacity for intellectual progress* is a most remarkable peculiarity of Man's psychical nature. The instinctive habits of the lower Animals are limited, are peculiar to each species, and have immediate reference to their bodily wants. Where a particular adaptation of means to ends, of actions to circumstances, is made by an individual, the rest do not seem to profit by that experience; so that, although the instincts of particular animals may be modified by the training of Man, or by the education of circumstances, so as to show themselves after a few generations under new forms, no elevation of intelligence appears ever to take place spontaneously, no psychical improvement is manifested in the species at large. In Man, on the other hand, we observe not merely the capability of profiting by experience, but the determination to do so; which he is enabled to put into action by the power which his Will (when properly disciplined) comes to possess, of directing and controlling his current of thought, by fixing his attention upon any subject which he desires to keep before his mental vision. This power, so far as we know, is peculiar to Man: and the presence or absence of it constitute the difference between a being possessed of power to determine his own course of thought and action, and a mere thinking automaton.

41. Man's capacity for progress is connected with another element in his nature, which it is difficult to isolate and define, but which interpenetrates and blends-with his whole psychical character. "The Soul," it has been remarked, "is that side of our nature which is in relation with the Infinite;" and it is the existence of this relation, in whatever way we may describe it, which seems to constitute one of the most distinctive peculiarities of Man. It is in the desire for an improvement in his condition, occasioned by an aspiration after something nobler and purer, that the main-spring of human progress may be said to lie; among the lowest races of mankind, the capacity exists, but the desire seems dormant. When once thoroughly awakened, however, it seems to "grow by what it feeds on;" and the advance once commenced, little external stimulus is needed; for the desire increases at least as fast as the capacity. In the higher grades of mental development there is a continual looking-upwards, not (as in the lower) towards a more elevated Human standard, but at once to something beyond and above Man and Material Nature. This seems the chief source of the tendency to believe in some unseen existence; which may take various forms, but which seems never entirely absent from any race or nation, although, like other innate tendencies, it may be deficient in individuals. Attempts have been made by some travellers to prove that particular nations

are destitute of it; but such assertions have been based only upon a limited acquaintance with their habits of thought, and with their outward observances; for there are probably none who do not possess the idea of some invisible Power, external to themselves, whose favour they seek, and whose anger they deprecate, by sacrifice and other ceremonials. It requires a higher mental cultivation than is commonly met-with, to conceive of this power as having a spiritual existence; but wherever the idea of Spirituality can be defined, this seems connected with it. The vulgar readiness to believe in ghosts, demons, &c., and the vagaries of the so-called 'Spiritualists' of recent times, are only irregular, or depraved manifestations of the same tendency. Closely connected with it is the desire to participate in this spiritual existence; of which the germ has been implanted in the mind of Man, and which, developed as it is by the mental cultivation that is almost necessary for the formation of the idea, has been regarded by philosophers in all ages as one of the chief natural arguments for the immortality of the soul.

CHAPTER III.

ON THE MINUTE ANATOMY OF THE CONNECTIVE TISSUES. CELLS AND THEIR DERIVATIVES.

42. The whole substance of the body in many of the lower forms of Animal Life, and the elementary parts from which the several tissues are formed in the higher, is composed of a soft gelatinous substance which was named *Sarcode* by Dujardin, *Protoplasm* by Reichert, v. Mohl and Remak, *Cytoplasm* by Kölliker, *Germinal matter* by Beale, and in its various kinds represents the 'Physical Basis of Life,' of Huxley.* It is transparent and homogeneous and may be compared to white of egg. It usually presents a number of minute granules distributed through its substance, which are derived in part at least from the materials it has absorbed. It may exist in the form of separate masses, varying in size from points scarcely perceptible with the microscope, to such as are visible to the naked eye, or in the form of layers or sheets lining the interior of cells and vessels. When at rest it is probable that masses of protoplasm assume a spherical form, but under all ordinary circumstances they are more or less flattened and exhibit certain movements, and present the phenomena of growth, nutrition, and reproduction. The movements witnessed in Protoplasm are of two kinds, both of which are rendered conspicuous by the molecules in its substance. The first is a vibratory, quivering, or dancing movement of the granules resembling closely those trembling movements of resinous and other inorganic particles suspended in fluids, which, having been first described by Robert Brown, are sometimes called Brownian motions. Such vibratory movements are chiefly seen in spherical masses of Protoplasm, and cease when these are undergoing changes of form or place. The second kind of movement demonstrates the contractility of protoplasm, which, as is shown by experiments on the pigment cells of the Chameleon and various Amphibia,† Fishes, and Cephalopoda in

* The best account of Protoplasm is given by Kühne in his essay entitled "Das Protoplasm," Leipzig, 1864; but the reader may refer with advantage to the essay on Cells by Stricker in his "Manual of Histology," Syd. Soc. Translation, vol. i. p. 1, where the chief authorities on this subject are cited; to Huxley's lecture on The Physical Basis of Life, in his "Lay Sermons and Addresses;" and to Haeckel's work on "General Morphology."

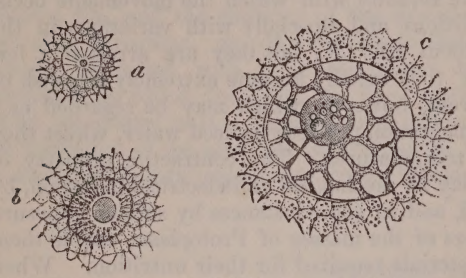
† Lister, "Philosoph. Transact.," 1858.

which the sarcode contains coloured granules, is under the control of the nervous system. The masses change their shape, becoming elliptical or ovoid, and flattened or irregular, owing to the thrusting out of processes, and these may be either withdrawn or may drag the rest of the body after them, so that in detached masses locomotion is effected. The processes may vary in shape from rounded elevations or swellings but slightly projecting from the general surface, to long and extremely delicate threads, and portions may then become altogether detached. The rapidity with which the movements occur differs with the surrounding conditions, and especially with variations in the temperature, being greatest at about 100° F., but they are arrested a few degrees higher (110° F.). At 32° they usually become extremely sluggish or cease altogether. The ova of trout, however, which may be regarded as a kind of Protoplasm, undergo segmentation perfectly in iced water, whilst they soon cease to move at ordinary temperatures. The contractile property of Protoplasm can be brought into play by mechanical and electrical irritation, by the application of chemical stimuli, and in some instances by sudden exposure to light.* The locomotive powers of the masses of Protoplasm enable them to search for, and procure, the materials required for their nutrition. When such materials are met with, the Protoplasm extends itself over and embraces them, the opposite surfaces coalescing, so that the foreign body is entirely included; its nutritive parts are then extracted, and the remainder, if any, is cast away by the retreat of the Protoplasm from it. The reproduction—or rather multiplication—of such masses is effected by the detachment of a larger or smaller portion of the parent mass, the two parts separating to obtain the substances requisite for their own growth and nutrition. Chemical examination of Protoplasm shows that it contains a considerable proportion of myosin, and in some instances, protagon, glycogen, and cholesterin have been found to be present. Protoplasm, presenting slight but unimportant differences from the general description above given, is found to form the contents of all Vegetable cells, at least in their early condition, to constitute the essential part of a great group of organisms which have been associated together by Haeckel under the name of Protista, and include such forms as the Flagellata, Diatomaceæ, Myxomycetæ, and Foraminifera, the last of which recent researches have shown to form a thin, but very widely spread, layer on the bed of the ocean at all depths. And, finally, it forms the living material in the interior of all animal cells, and to its presence the active processes they exhibit are essentially due. In the very simplest forms of Animal Life, as in the Monera, no differentiation of structure is visible in the Protoplasm of which they are composed. But in most of the Amœbæ and Foraminifera; in the ovum at an early stage of its development; in the free floating corpuscles known as the white corpuscles of the blood; in granulation cells and pus corpuscles; in the corpuscles of the ductless glands; in osteoblasts, and elsewhere, the small masses of Protoplasm contain a nucleus; and such bodies may be conveniently designated by the term employed by Haeckel of *Plastids*. In most cases the outer surface of the Protoplasm has undergone a certain, though often very slight, degree of consolidation. And when this consolidation has proceeded so far as to form a thin membrane around the protoplasmic mass and nucleus, an *encased cell* is formed, the mature forms and characters of which differ considerably in plants and animals, though the history of their development is nearly the same.

* Engelmann, Pflüger's "Archiv," 1879, Band xix. p. 1. F. Darwin, "On the Contractile Filaments of the Teasel and of Amanita," in "Quart. Journ. of Mic. Sci.," July, 1877, and January, 1878, p. 74.

43. The observations of Strasburger* have shown that in the evolution of the *vegetable* cell the nucleus first appears as a simple point. Around this as a centre a transparent spheroid of protoplasm forms (Fig. 12, *a*), the outer surface of which becoming slightly condensed, constitutes the limit of the newly formed cell.† As this increases, a new distribution of the protoplasm occurs, which becomes reticulated (Fig. 12, *b*), a thinner fluid, or cell-juice, occupying the meshes. The nucleus, originally spheroidal, changes its form and position, becoming oval or discoid, and more or less eccentric (Fig. 12, *c*). The young cells at first separate, approximate to each other, and at length touch at certain points; and wherever this occurs a lamella of cellulose is deposited between them—a substance which ultimately encloses the whole cell. The cell is now complete. The nucleus appears to represent the cell on a smaller scale, having its own limiting membrane and its own reticulated protoplasm. All evidences of activity in cells are due to the protoplasm they contain; for if this be reduced to inactivity by desiccation, by exposure to moderate heat, or by withdrawal of oxygen, the cell remains quiescent, and no secretory, motor, or other form of activity is exhibited. In compound organisms composed of many cells every cell, in maintaining its own nutrition, ministers to the functional activity of the special tissue to which it belongs, and is subservient to the wellbeing of the organism at large.

FIG. 12.



Free-cell development exhibited in the growth of the cells of the albumen of *Phaseolus multiflorus*.

a, represents an early stage of development. The nucleus is seen to be still punctiform and the cell is represented by a clear spheroid slightly granular in the interior, and limited by a well-defined line.

In *b*, the nucleus has become vesicular, the protoplasm of the cell presents a reticulated aspect.

c, represents a fully-developed cell. The nucleus is vacuolated, the protoplasm is more distinctly differentiated into a reticulated tissue containing the cell-juice in its meshes; the cell-wall presents a double contour.

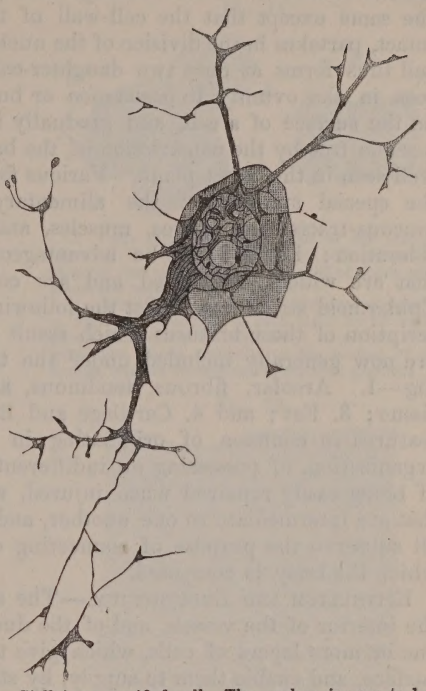
44. The structure of an *animal* cell is essentially similar to that of a vegetable cell, and they frequently arise in the same way. When mature it is composed of a more or less firm and consistent limiting membrane, apparently composed of some modification of protoplasm representing the cellulose *cell-wall* of the Plant Cell, and like it enclosing a reticulated mass of protoplasm—a nucleus and cell-contents which vary with the organ from which the cell has been taken. The consistence of the cell-wall may, as in the case of the hepatic cells, be only slightly, if at all, denser than the general protoplasm of the cell, or, as in cartilage cells, it may acquire great firmness and thickness. Occasionally it presents pores, as in the ovum of the Fish and the cells of the notochord; and it may be deficient at some part of the surface, as in the cells covering the intestinal villi. It is often prolonged in the form of cilia, or of processes rendering it more or less stellate in form. A *nucleus* is rarely, if ever, absent in young cells. It may be spheroidal, oval, fusiform, or discoid in shape, and may be centric or eccentric (Fig. 13). It consists of a delicate sac, the cavity of which is traversed by numerous anastomosing fibres. According to the closeness and form of the fibres, the appearance presented is that of a net, or the honeycombed aspect of a sponge. In either case the meshes of the nuclear plasma are filled with nuclear juice. The

* "Ueber Zellbildung und Zellthielung," Jena, 1875.

† The primordial utricle of Hofmeister.

ibres often present slight thickenings at certain points, as well as bright pots, which are the expression of the optical sectional view of the fibres, whilst at other points the meshes are loser, giving rise to local thickenings which Klein believes to be the nucleoli; a view that is not incompatible with the spontaneous movements hat have been observed in them.* The *contents of cells* like those of he nucleus are generally divisible nto two parts, Protoplasmic substance which appears in the form of granular anastomosing filaments, bands, or nembranes traversing the interior, and extending from the outer surface of the nucleus to the periphery of the cell; and Paraplasm, which varies in characters and attributes with the special tissue or organ from which he cell has been taken, being sometimes transparent and colourless, sometimes charged with pigment, and sometimes containing the special secretion of a gland; in some instances he protoplasm seems to become almost wholly replaced by fat, or acquires he highly differentiated properties of nerve or muscle. In young cells, the protoplasm is mingled with cholesterin and lecithin, and in many instances with glycogen. The mode of origin, or genesis, of cells varies in different instances. The method to which reference has just been made is termed *free-cell formation*, the cells developing independently in a blastema that has been formed by pre-existing cells. It is seen in the Myxomycetes,† and Legros and Onimus‡ and Montgomery§ have shown that it also occurs in the higher animals, since, if small sacs made of goldbeater's skin or parchment-paper be filled with the serum of a blister, filtered to remove all morphological elements and placed beneath the skin of a rabbit, a large number of leucocytes appear in the fluid in the course of twenty-four hours. This mode of development is, however, comparatively rare, and animal cells in general arise by one of three methods, by endogenous multiplication, by fission, or by germination.

Fig. 13.



Stellate or ramified cell. The nucleus is seen to be vacuolated, the protoplasm forming a network which contains a clear juice in its nucleus.

In *endogenous multiplication* the nucleus primarily divides into two, then into four, eight, or more parts, each segment attracting around it a spheroidal portion of the protoplasm of the mother-cell. The mother-cell usually grows

* By Auerbach, "Organolog. Studien," Breslau, 1874. Brandt, "Archiv. f. Mit. Anat.," Band x. Eimer, idem, Band xi. Kidd, "Q. J. Mic. Sci.," 1875, p. 133. Klein observed that the meshes of the intra-nuclear fibres are closer and more compactly arranged near the periphery of the nucleus forming an internal filamentous membrane, sometimes separated by a hyaline space from the proper membrane of the nucleus. The nucleus as a whole has been observed under favourable circumstances to execute movements of an amœboid character. (Kidd, op. cit. p. 133.)

† De Bary, "Die Mycetozoen," 1864.

‡ "Journal de l'Anatomie," 1867. § Idem, 1868.

to some extent; but the daughter-cells growing more rapidly, ultimately burst the resisting membrane that confines them and are set free. This method is seen in fat and cartilage cells (Fig. 31). In *fission*, the process is the same except that the cell-wall of the parent-cell instead of remaining intact, partakes in the division of the nucleus and cell-contents, and the mother-cell thus forms at once two daughter-cells. This method of development is seen in the ovum. In *gemmation* or budding, one or more swellings appear on the surface of a cell, and gradually increasing in size are nipped off and become free by the constriction of the base. This method of development is well seen in the yeast plant. Various forms of cells will be described when the special subjects of the alimentary, respiratory, and genito-urinary mucous-tracts, the nerves, muscles, and glandular organs are under consideration; but it will be advantageous to consider here various forms that are widely distributed and are collectively known as Epithelial and Epidermoid structures, whilst the following sections will be devoted to the description of those textures which result from the metamorphosis of cells, and are now generally included under the title of Connective Tissues, embracing—1. Areolar, fibrous, tendinous, and ligamentous tissues; 2. Elastic tissue; 3. Fat; and 4. Cartilage and Bone. These tissues all present the features in common of originating in cells, of presenting a low type of organization, of possessing an indifferent supply of bloodvessels and nerves, of being easily repaired when injured, whilst they frequently present forms that are intermediate to one another, and finally, as their name implies, they all subserve the purpose of connecting or supporting the other textures of which the body is composed.

Epithelium and Endothelium.—The skin, mucous and serous membranes, the interior of the vessels, and of the ducts of many glands, are covered with one or more layers of cells, which give to these parts a smooth and uniform surface, and enable them to supply, by structures capable of easy renewal, the losses they experience from the friction to which they are constantly subject. The innermost recesses of glandular organs are also lined by cells, the function of which appears to be the separation from the blood, or the formation from the materials supplied by that fluid, of the secretion proper to each. Four principal kinds of cells have been distinguished by microscopists, forming by their juxtaposition, tesselated or pavement, cylindrical or columnar, spheroidal or glandular, and ciliated epithelium, and the contours of the cells may be brought into view by immersing the fresh membrane for a few minutes in a one-half or one-quarter per cent. solution of nitrate of silver, and then washing in distilled water.

c Fig. 14.

Tesselated Epithelium from the abdominal surface of centrum tendineum of rabbit, strongly coloured after treatment with nitrate of silver.—*a*, dark silver lines of the interstitial substance of the endothelial cells; *b*, cell-substance; *c*, nucleus. The smaller cells lie over a capillary lymphatic. The dark spaces are pseudo-stomata.

Tesselated epithelium is found as a single layer of flattened cells in the interior of the vessels and synovial and serous membranes (Fig. 14), and here receives the name of Endothelium. The cells are seen to be flat, and are often either sinuous in outline, or are rendered polygonal by mutual pressure. They possess a cell-wall, and

a distinct nucleus, which are best seen after staining with silver nitrate and hæmatoxylin. As a multiple layer this form is well seen in the skin (Fig. 18, *a*, *b*),

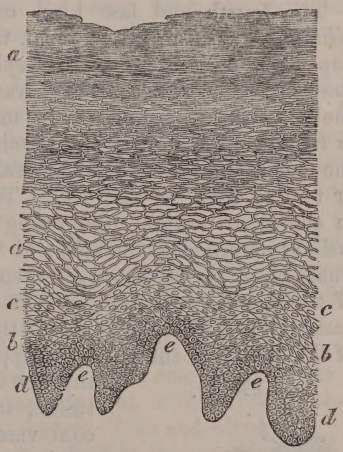
C. Cells from the upper part of the mucous layer.—*a*, flattened and lamelliform cells resembling those of the corneal layer; *b*, nuclei of these cells, small and with festooned border.

D. Cells from the deep part of the mucous layer.—*a*, four cells adhering to each other by an amorphous substance; *b*, thin nuclei, which are elongated, are placed vertically to the surface of the dermis, and are surrounded by pigment granules.

FIG. 18.



Vertical section of the epidermis of the skin of the palm of the hand, × 100.—*a*, *a*, thick corneal layer composed of a large number of superimposed cells without nuclei; *b*, *b*, mucous layer formed of nucleated cells; *c*, upper part of this layer which is separated from the corneal layer by an undulating line; *d*, *d*, projections from the inferior surface corresponding to the depressions between the papillæ of the dermis, *e*, *e*.

where it constitutes the thick epidermis. The action of a blister splits the epidermis into two portions; a deeper one—the rete mucosum—in which the cells (Fig. 16, *b*, and Fig. 18, *b*), being in an early stage of their development, are more or less soft and rounded, and remain attached to the dermis; and a superficial portion — stratum corneum or epidermis—which forms the blister, and is composed of flattened cells firmly cohering together (Fig. 18, *a*, shown isolated in Figs. 15 and 17). The cells of the rete mucosum are the chief seat of the pigmentary deposit characteristic of the skin of the Negro and of the darker portions of the body of fair-skinned races. In some parts the cells are serrated at their margin (Fig 19).

FIG. 19.

Epithelial Cell (ribbed cell of the Rete Malpighii).

The second form of cell—the *columnar*—occurs throughout nearly the whole of the alimentary canal. The cells are arranged vertically to the surface, as seen in Fig. 17, D, and are attached to the subjacent membrane by their small extremity. They possess a distinct nucleus,

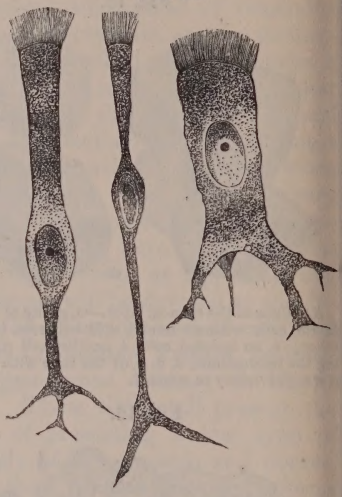
cell-wall, and cell-contents, and their mouth in those lining the small intestines is closed by a striated membrane, the striæ being by some believed to represent fine pores, permitting the passage of oily and albuminous fluids.

Fig. 20.

Cup, or *Goblet-Cell.*

Spheroidal epithelium is best seen in the acini of glands. The shape of the cells is expressed by their name: but the presence of a cell-wall is in many instances doubtful. They appear to be masses of germinal matter, and have been observed to execute spontaneous movements. Both spheroidal and columnar epithelial cells are also capable of gliding over one another, and thus changing their position without becoming detached. The bladder, for instance, when contracted presents eight or nine series of cells, but when distended only two or three.*

Fig. 21.



Various forms of *Ciliated Epithelial Cells* from the trachea of a cat.

The fourth and last kind of cell—the *ciliated*—varies much in form, though perhaps the cylindrical or sub-cylindrical is the most common. It is characterized by the presence of a number of minute cilia, or hair-like processes of the contained protoplasm of the cell, which project from the basal border of the cell-wall, varying from one or two to fifty for each cell. These, during life, are in continual motion, performing rapid vibratory or lashing movements, the effect of which is to drive any small body in contact with them towards the outlet of the body. Such cells are found in the respiratory passages, with the exception of the finest ramifications of the bronchial tubes; in the upper part of the vagina, the uterus, and the Fallopian tubes; in the vasa efferentia, coni vasculosi, and first part of the excretory duct of the testis; and lastly, on the choroid plexus of the lateral ventricles and in the central canal of the spinal cord in young animals. In some Vertebrata they also exist near the commencement of the urinary tubuli, and in the frog in the mouth. The cause of the movement is unknown; it

* E. Neumann ("Archiv f. Mic. Anat."), Band xii. p. 570, finds that the œsophagus and upper part of the digestive canal in fœtuses, aged from 18–32 weeks, is covered with ciliated epithelium. A few ciliated cells were also found in the stomach and in a narrow line extending from the epiglottis to the foramen cæcum on the dorsum of the tongue. The cilia are either seated on a homogeneous bright basal border, or on a bright basal border presenting the striation characteristic of the border of the intestinal epithelium, and he thinks the cilia and the basal rods are continuous. Bochdalek observed certain tubes near the foramen cæcum to be also lined by ciliated epithelium.

is remarkable that it should persist long after the general death of the body. A very peculiar form of cell, termed *Cup, or Goblet-Cell* (Fig. 20), appears scattered over parts that are usually covered by columnar and ciliated cells. According to Klein,* they are only the empty shells of the ordinary ciliated cells, the substance of which has undergone conversion into mucin. In certain parts of the body—as in the choroid coat of the eye, the lungs, and bronchial glands, and in the deep or Malpighian layer of the epidermis of the Negro—cells are found, termed chromoblasts, containing *pigment.* The shape of these cells varies from the most regular hexagonal to extremely irregular branched and caudate forms. They usually possess a distinct nucleus, and the melanin is scattered through the otherwise clear protoplasmic cell-contents in the form of minute granules. Some pigment-cells, as those in the skin of the Frog,† are capable of undergoing remarkable changes in their form and in the distribution of the pigment granules in their interior. They may contract into spheroids, or may expand into a stellate form, with numerous irregular, branched, anastomosing, and gradually attenuating processes; and the pigment granules may either accumulate around the central nucleus, or be distributed through the protoplasm. According to Lister, their concentration follows exposure to the action of light, section of the nerve, and the death of the animal. On the other hand, the molecules diffuse themselves through the cell-processes, when the animal is kept in darkness, and when the skin is irritated. Hering‡ and Hoyer think the movements of the granules are essentially dependent upon disturbances or variations of the circulation due to the action of the vaso-motor nerves, by which they are therefore indirectly influenced. Pouchet,§ however, believes he has traced nerve fibrils directly into the sarcodal substance of the chromoblasts.‖ Saviotti¶ has observed the migration of the pigment-cells of the wall of the frog's foot into the bloodvessels after irritation, the time occupied in the transit of the cells through the walls of the bloodvessels being about twelve hours. M. Tschaussow** observed, on the contrary, the passage of a pigment-cell *out* of a vein and its division into two in the tissues. When the cell is crushed the black particles escape and exhibit Brownian vibratory or quivering movements. When viewed singly and with high powers the particles appear transparent and nearly colourless. The colouring matter or melanin is insoluble in water and most reagents, but it dissolves in weak alkalies. It is not bleached by chlorine. It contains iron and nitrogen.

45. *Areolar, Fibrous, and Elastic Tissues.*††—Ordinary *connective tissue* in its fully-developed form may be shortly defined to consist of plasmatic corpuscles scattered through a fibrillar matrix. Amongst the principal examples

* "Handbook for the Physiological Laboratory," 1873, p. 23.

† See the paper of Lister, in "Phil. Trans." 1858; of MM. Hering and Hoyer, in the "Centralblatt," 1869, p. 49; of Brücke, in his "Vorlesungen über die Physiologie," 1874, p. 440; and of G. Pouchet, "Journal de l'Anatomie," 1876, p. 1, who has named such cells 'Chromoblasts.' In some instances the pigment instead of being like melanin in the form of granules, is dissolved in the sarcode, which then presents various shades of red, orange, or yellow. Sulphuric acid has no action on melanin, but changes the tint of the other pigments successively to green, blue, and violet.

‖ In some instances the coloration perceptible in animal tissues is due to absorption of certain rays, a property that Pouchet has termed *Cœrulescence.* It is to this that the blue colour of the iris is due, the tint of a thin lamina of cartilage, and the reason that the veins appear blue through the skin, though conducting red blood.

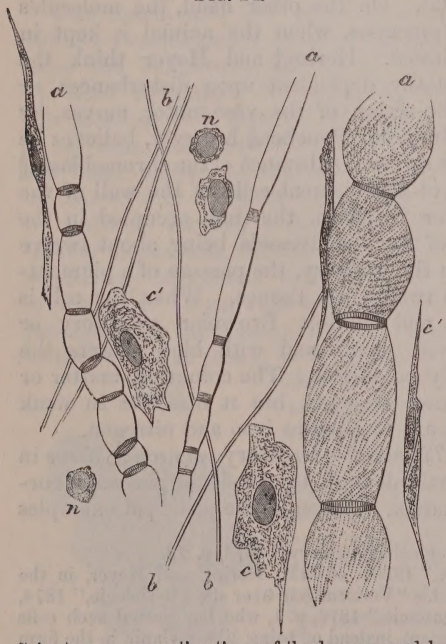
†† For a good account of Connective Tissue see Ranvier, "Traité Technique d'Histologie," 1875-78, p. 325.

of ordinary connective tissue met with in the body we may include the various structures termed tendons, ligaments, fasciæ, aponeuroses, periosteum, and perichondrium; the investing membranes of many organs, as the dura mater, pericardium, tunica albuginea of the testis and of the ovary, and the sclerotic and corneal coats of the eye. It also forms the basis of the dermis, of mucous, serous, and synovial membranes of the chorion, the sheaths and tunics of vessels, of amorphous membranes like the hyaloid humour of the eye, and of the envelopes of glandular follicles. These all present a general similarity of structure and chemical composition, though differing in minor details. Connective tissue may present itself in several forms as, first, *loose connective tissue*, such as occurs beneath the skin. Here, if a small quantity of silver nitrate or staining fluid be injected with a sharp-pointed syringe, and the little œdematous swelling removed and quickly placed under the microscope, it will be seen (Fig. 24) to consist of longitudinally striated fasciculi of connective tissue running in all directions, but separated by the liquid that has been forced in; sharply-defined fibres of elastic tissue, partly running parallel to the fasciculi, and partly coiling round them; large flat cells, fat cells, and small masses of protoplasm resembling the white corpuscles of the blood. The *fasciculi* (*a*) vary from the 1-10,000th or less to 1-2000th in diameter, especially if acetic acid has been added, which causes them to swell up, and exhibit annular or spiral constrictions, corresponding to the lines pursued by the elastic fibres which are not acted on by this reagent. When acted on by picric acid the fasciculi can easily be broken up into their constituent fibrils, which are found to be excessively delicate cylinders. The fasciculi exert a double refractive power on light.

Fig. 24.



Subcutaneous connective tissue of the dog, prepared by the interstitial injection of a 1-1000 solution of silver nitrate, stained with picrocarminate and mounted in glycerin slightly acidified with a little formic acid.—*a*, connecting tissue fasciculi with annular fibres surrounding them at intervals; *b*, elastic fibres; *c*, flat cells seen *en face*; *c'*, flat cells seen in profile; *n*, lymphatic cells.

The *elastic fibres* (*b*) stain yellow with picric acid and with iodine; they vary greatly in size, branch and anastomose, run straight or in a more or less undulating or spiral manner. They appear to be perfectly homogeneous, and have well-defined dark borders. The quantity present varies considerably in different situations in accordance with the different functions it has to fulfil. The *cells* belonging properly to the connective tissue are nucleated, large, granular and greatly flattened; some are polygonal and regular; others present amœboid movements (*c*); seen in profile they are fusiform. They appear to be attached to and to embrace the fasciculi at intervals. The *fat cells* and *lymphatic cells* are extraneous or accidental elements, and will be described in a subsequent section.

A second form of connective tissue is presented by the *tendons*. These are dense, strong, round or flattened aggregations of connective tissue by

means of which muscles are inserted into bone. They have an external investment of flattened epithelial cells, and are only feebly supplied with blood. On microscopical examination they are found to be composed of fasciculi of connective tissue, the fibres of which run in a nearly straight direction, and are invested by peculiar nucleated cells, which when slightly compressed assume a rectangular form (Figs. 25 and 27.) The cells are curved like the tiles of a house.* The cells present one or more longitudinal ridges (the elastic striæ of Boll, or 'crêtes d'empreinte' of Ranvier) (*e*), which are probably the projections of the cells into the spaces between adjoining fasciculi seen foreshortened, though they may possibly be the result of wrinklings of the cell-wall or of coagulation of the protoplasm. A few fine elastic fibres accompany the tendinous fibres. Transverse sections of tendons exhibit such stellate figures as are shown in Fig 25, and which were considered by Virchow to be formed by branched and anastomosing plasmatic cells, and to constitute channels for the conduction of nutritive fluid; though Henle regarded them as merely representing the interspaces between the parallel fasciculi of the tendon. Ranvier, the most recent inquirer, considers them to be the sections of the cells that have just been described. In the case of the serous and synovial membranes, which as Klein has shown may be regarded as dilatations of the lymphatic system, the connective tissue is so arranged as to constitute bags or sacs, the inner surface of which is, for the most part, lined by a single layer of flattened epithelial cells, forming an exquisitely smooth and polished surface, that materially facilitates the constant gliding movements to which these parts are subjected. Besides these, more rounded cells, termed 'germinating endothelial cells' by Klein, are found in certain regions, as will be more fully explained in the section on the lymphatic system. In the vitreous humour of the eye, and in the substance which constitutes the greater part of the umbilical cord, there exists a peculiar form of connective tissue, termed *mucous* or *gelatinous tissue*. The structure of the vitreous humour of the eye is difficult to determine, but it appears to be composed of a jelly-like fluid, contained in the meshes of a network of exquisitely fine filaments; it is doubtful whether any cells are present. In the cord the matrix is soft, transparent, and homogeneous as in the vitreous, but

* And have hence been compared to the paddle-wheel of a steamer, the connective tissue occupying the re-entering angles between the laminæ, and the nucleus being contained in the chief lamina. See Waldeyer "Archiv. f. Mic. Anat.," Band xi. p. 176; also Dr. Karl Mays, "Virchow's Archiv.," 1879, Band lxxv. p. 128, in which the bibliography of this subject is well given.

presents round, fusiform, or stellate cells, with branched and communicating prolongations scattered through it. This kind of connective tissue is found only in embryonic structures, or in organs retaining their embryonal characters. In mucous membranes the layer of connective tissue is much thicker and more vascular than in serous, frequently contains minute glands, and instead of a single layer, is covered by many layers of epithelial cells, of a more or less rounded or columnar form. In all instances mucous membranes constitute the walls of tubes or cavities having free outward communication. The interspaces between the fibres of connective tissue are believed by many to constitute the commencement of the lymphatic system, receiving the superfluous material poured out by the bloodvessels for the supply of the several textures, and gradually conveying it, at first through irregular spaces partially filled with protoplasmic masses or cells, but subsequently through proper tubes, to the thoracic duct, from whence it is again discharged into the blood. On boiling with water this tissue yields gelatin. The connective tissue is primarily developed from the mesoblast. Much difference of opinion exists in regard to the mode of origin of the fibres; some thinking that they are derived from the elongation and fibrillation of the protoplasm of the cells, whilst the recent observations of Ranvier seem rather to show that they result from the fibrillation of the intercellular substance without the direct participation of the cells, though the intercellular substance itself was of course originally formed by the cells. The elastic fibres are commonly believed to be the result of a direct deposit, or differentiation of the matrix, though Virchow thought they were the remains of the cells.

46. Elastic Tissue.—The *elastic tissue* that we have just seen to be mingled in small quantity with white fibrous tissue in situations where it is requisite that the latter should accommodate itself to changes of form, bulk, or position in the organs it invests, is sometimes met with in an almost pure state. In the vocal cords and the ligamenta subflava good examples are seen of this tissue, with scarcely any intermixture of white fibrous tissue. In the ligamentum nuchæ and the suspensory ligament of the penis, in the stylo-hyoid, thyro-hyoid, and crico-thyroid ligaments, and in the coats of the bloodvessels and lymphatics, both kinds of tissue are present in nearly equal proportion, though perhaps the elastic predominates; whilst in the subcutaneous and submucous areolar tissue, the elastic fibres, though numerous, form only a small part of the general mass. When examined under the microscope it is found to consist either of separate fibres, of bundles of fibres, or of broad membranous bands of a highly refractile and elastic substance. The fibres vary indefinitely in size, but have sharply-defined dark borders, and appear to be abruptly broken off at their extremities. They may anastomose and branch, and where the fibres are broad and membraniform, and the anastomoses close, a thin tissue results, as in the lining or fenestrated membrane of the arteries, which presents a continuous sheet with only here and there minute holes or spaces. The arrangement of its bloodvessels and nerves, which are very few in number, is not accurately known. The fibres are reddened with Millon's reagent, and give the xanthoproteic reaction. They are not acted on by

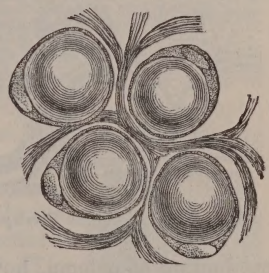
Fig. 28.

Yellow or *Elastic Fibrous Tissue*, from ligamentum nuchæ.

acetic acid. When long boiled they yield a little modified gelatin. Elastic tissue fulfils important functions in the vascular system—to which attention will hereafter be called—and it frequently occurs in situations where its physical properties enable muscular tissue to be dispensed with, as in the ligamentum nuchæ of the larger quadrupeds. Occasionally, though more rarely, it appears as the antagonist of muscular effort, as in the chordæ vocales, and typically in the hinge of the shell in the Lamellibran chiata.

47. Adipose Tissue.—This form of tissue is extensively distributed through the animal kingdom, and consists of large cells filled with oil, which in good specimens are individually separated from one another, as well as collected into lobules by delicate trabeculæ of connective tissue (Fig. 29). It is more freely supplied with blood than most of the other forms of cellular or connective tissue, and according to Toldt the one or two arterial branches distributed to a given lobule do not communicate with those of adjoining lobules, whilst the blood is returned by a pair of veins accompanying the arterioles. The cells, though varying much in size, average the $\frac{1}{500}$th of an inch in diameter, and are rendered polygonal by mutual pressure; they are composed of a cell-wall of considerable thickness, lined by a layer of protoplasm, in which an eccentric nucleus with several nucleoli is imbedded, and which surrounds a clear, perfectly transparent, and highly refractile drop of oil. The connective tissue uniting the lobules is sometimes small in quantity, and exceedingly delicate, as in the fat that surrounds the kidney, and in the marrow of bones, in which free-cells may be observed; whilst in other instances, as in the subcutaneous layer of fat, it is possessed of much firmness, and is very dense. Nerves may be observed to accompany the vessels distributed to fat lobules, but their mode of termination is unknown.* Toldt describes the lymphatics of fat as forming wide-meshed capillary plexuses, but has been unable to discover that they possess any definite arrangement. Adipose tissue is absent in the brain, lungs, liver, and in the delicate skin of the eyelids, of the prepuce, scrotum, and nymphæ. In all these regions, however, oily globules may be seen on making fine sections. The absolute amount of fat in a well-nourished man amounts to about $\frac{1}{20}$th of the weight of the body. Infancy, mid-age, warmth, abundant food, especially of a saccharine or oleaginous nature, freedom from mental anxiety, castration, indolent habits, and inherited constitutional peculiarities, are all circumstances predisposing to the accumulation of fat. It is probable that every form of cell may become infiltrated with fat, as a stage or form of degeneration. Fat fulfils the following important objects in the animal economy:—It diffuses pressure, and is, therefore, largely developed on the palms of the hands, soles of the feet, buttocks, and female breast. By its disposition beneath the skin generally, it forms a warm investment for the body that materially diminishes the loss of heat by radiation and conduction; at the same time it gives a smooth, flowing, and agreeable contour to the surface which otherwise, especially near the joints, would present hard and angular outlines. It forms an elastic pad, or cushion, in the orbit, on which the eye can rotate; and in the heart, by filling up the interstices of the vessels and the irregularities of its surface, it fulfils a similar function, enabling this organ to perform its ceaseless move-

Fig. 29.



Four fat cells, with intervening connective tissue.

* Toldt, "Lehrbuch der Gewebelehre," 1877, p. 180.

ments with the least possible amount of friction. It confers lightness, and probably a certain degree of elasticity, on the bones—as well, indeed, as on all other tissues into the composition of which it enters. It constitutes a storehouse or reserve fund of hydrocarbonaceous material, which, when required by the economy, can readily be absorbed into the blood; the process of absorption being facilitated—as Matteucci has shown—by the alkalinity of the fluid that moistens the outer surface of the cells. Lastly, if we may judge from its constant presence when these processes are taking place, it plays an important part in the acts of nutrition, growth and development. Its sp. gr. is 0.924.

According to M. F. Czajewicz,* the cells of adipose tissue originate in the corpuscles of ordinary connective tissue. These, in any part that is about to become the seat of the deposit of fat, increase in size, assume a spherical form, and become filled with a mist of small fat drops (Fig. 30, *a*). At a stage slightly more advanced (*b*), the mist becomes condensed into small drops, which gradually acquire a larger size and greater distinctness (*c*), and ultimately blend into one large oil globule (*d*). Toldt, however, maintains that fat cells in the earliest stages of their development have no cell-wall, and constitute a tissue quite *sui generis* and distinct from connective tissue. In the later stages, the nucleus of each corpuscle, though still discoverable on careful examination, is generally pressed to one side, and is to a great extent obscured by the oily contents of the cell. Experiments made with picrocarminate of ammonia, or by means of the artificial production of œdema, however, not only demonstrate its presence, but also that it is surrounded by the remains of the protoplasm originally filling the cell, which expanded by the oil globule forms a thin layer beneath the secondary cell-wall, and which may be regarded as still playing an active part in the deposition or absorption of the oily matter.† When an animal is starved the oily material is continuously withdrawn from the cells, and its place is supplied by a serous fluid, the cells still preserving their round form. If now abundant food be given, a series of changes similar to those above described may be observed, the cells becoming filled at first with minute oil globules, which afterwards coalesce to form one of large size. If inflammation is established in adipose tissue by the injection of solution of iodine, or other irritant, the endogenous formation of cells can be very distinctly seen (Fig. 31). After death the cells often present crystalline stellæ.

48. Cartilage.—Cartilage presents two forms: the temporary and the permanent; the former exists in considerable quantity in the fœtus, making its first appearance in the vertebral column between the sixth and eighth week of fœtal life, and subsequently occupying the position and constituting the founda-

* Reichert's "Archiv," 1866, Heft iii. p. 289.

† Ranvier, 'Histologie du Système Nerveux," t. i. p. 117.

tion of the principal bones of the skeleton, certain portions of the vault of the cranium alone being excepted. The permanent or hyaline cartilage of adults is well exemplified in the cartilage covering the articular surfaces of bones, in the costal cartilages, and in the cartilaginous rings of the trachea. In all these situations it consists of a translucent bluish or yellowish solid mass, possessing great elasticity, and composed essentially of cells distributed through a matrix (Fig 32). The *Cells* are masses of protoplasm, and are contained in cavities named chondroplasts, which they completely fill. In the earlier periods of development, when the tissue is named *embryonal* cartilage, the cells are spheroidal and nucleated, and are almost in contact with each other; but in the later periods of development, in what is termed *fœtal* cartilage, the matrix or intercellular substance is much increased in quantity, and the cells become more or less compressed from mutual pressure. In *adult* cartilage an investing capsule (Fig. 33) forms around the cell which separates it from the matrix, and often presents concentric layers. Under certain circumstances the cells of cartilage have been observed to perform movements—contracting, for example, when an electric current is transmitted through them, or when sections are exposed to the action of water; but such movements are at most but slight and feeble. Near the margin of articular surfaces, and in close proximity with synovial membrane, the cartilage cells not unfrequently present transitional changes of form into the cells of connective tissue.* The cartilage capsules near the surface in articular cartilage are capable of being injected with coloured fluids, and therefore possess juice-canals communicating with the surface; and when the pressure is increased it is believed by some† that fine canals may be brought into view effecting a communication between neighbouring capsules. The *matrix* in the permanent or *hyaline* cartilages of the joints appears at first sight to be a homogeneous and structureless material; but by special treatment, as with a 10 per cent. solution of common salt, baryta water, and some other reagents, a fibrillar structure is brought into view.‡ Ordinary articular cartilage is thickest where the pressure is greatest, and the cells are found to be somewhat flattened near the free surface, irregularly distributed in sets of from four to eight or more near the centre, and perpendicularly placed in that part which lies nearest the bone. Embryonal cartilage is always isotropous, as is also the middle layer of articular cartilage; but the superficial and deep layers are doubly refracting.§ In the elastic or reticulated cartilage of the ear, epiglottis, and cartilages of Santorini and Wrisberg, the matrix is of a yellowish colour, and pervaded with elastic fibres (Fig. 34). From this form of tissue the transition is easy to the *fibro-cartilages* exemplified

in the symphysis pubis, the intervertebral substance, the interarticular cartilages of the knee and other joints, the glenoid and cotyloid ligaments, and the cartilages lining the grooves for tendons; in all of which the matrix is almost entirely converted into firm and close-set interlacing connective tissue fibres. The costal, as well as the fibro-cartilages are invested by a dense layer of connective tissue, containing vessels termed the periosteum; and although the two tissues may be separated by prolonged maceration, they are structurally continuous with one another. The nutrition of cartilage when in thin laminæ is sufficiently provided for by the process of imbibition; but in the case of the thicker masses it is effected partly by minute vessels which, proceeding from the perichondrium, dip into its outer surface and form loops, and partly by larger branches which traverse its substance, and lie in channels lined by a process of the perichondrium. The tissue is, however, essentially extravascular. No nerves or lymphatics have been hitherto traced into the substance of cartilage; and it appears to be nearly insensible. The exquisite pain accompanying ulceration of joints is probably referable to irritation of the nerves supplying the subjacent bone. On drying it loses about 70 per cent. of water; on being subjected to prolonged coction in water it yields chondrin. The organic basis from which the chondrin is derived constitutes about 30 per cent. of fresh cartilage; and the inorganic substances, of which the sulphates of potash and soda constitute the major part, do not amount to more than 2·5 per cent. (Hoppe-Seyler). The inorganic constituents of rib and knee-joint cartilage differ remarkably.* Permanent cartilage is employed in the construction of the body chiefly on account of its resiliency, as in the ribs, trachea, and bronchi, and the joints. In the latter situation its smoothness, rendered greater by the synovia, prevents free movement and reduces friction.

less perfectly enclose the cavities of the head, chest, and pelvis; and by their hardness and elasticity constitute an efficient protection to the important organs therein contained. They are divided, according to their form, into long, short, irregular and flat bones. In the long bones the shaft is pierced by a central canal, which runs continuously from one extremity to the other; and the hollow cylinder which surrounds this is very compact in its structure. On the other hand, the dilated ends of the bone are composed of a spongy or cancellated structure, which is made up of osseous lamellæ and fibres interwoven together. The arrangement of these is by no means irregular or fortuitous, but exquisitely adapted for the mechanical functions the bones have to perform, and in exact accordance with theoretical requirements;* a multitude of minute chambers or cancelli freely communicating with one another and with the cavity of the shaft being formed, whilst the whole is capped with a thin layer of solid bone. In the flat bones of the head, and less distinctly in the scapula and ilium, we find the two surfaces composed of solid osseous texture, with more or less of cancellated tissue called the *diplöe*, interposed between the layers. This, however, is sometimes deficient, leaving a cavity, as in the frontal sinuses. Finally, we frequently meet (especially in the ethmoid and sphenoid bones) with thin lamellæ of osseous substance resembling those which elsewhere form the boundaries of the cancelli. These consist of a single layer of osseous substance, and are not penetrated by vessels, but are nourished by those ramifying on their surfaces; and they consequently exhibit the elements of the osseous substance in their simplest form. It will be desirable, therefore, to commence with the description of these.

50. When a thin natural lamella of this kind is examined, it is found to belong to the doubly refracting tissues, and to be chiefly composed of a nearly homogeneous indistinctly fibrous substance. Scattered through this are a number of dark spots presenting an oval form, and giving off from their sides and extremities numerous radiating processes of extreme minuteness, and frequently of considerable length. The dark spots are small cavities termed *lacunæ*, and the branched processes, or *canaliculi*, are tubular channels, which, though far too small to convey blood corpuscles, yet, through the agency of the protoplasm, bring the fluid elements of the blood, or matters secreted from them, into close relation with every part of the tissue. The size of the lacunæ is to some extent proportionate to that of the blood corpuscles, being large in reptiles and fish, and smaller in the higher classes of vertebrata. In man their long diameter is about 1-1800th of an inch, and their short 1-6000th of an inch. Every lacuna is occupied in the living bone by a mass of protoplasm which sends prolongations into the canaliculi, and is the nutritive centre of the surrounding osseous substance. If, instead of a thin lamella of bone, sections of one of the long bones be examined, it will be found that the penetration of the tissue by bloodvessels renders a peculiar arrangement of the lacunæ and canaliculi requisite. The solid osseous texture which forms the shaft is covered by a strong and firm layer of connective tissue termed the 'periosteum,' in which numerous bloodvessels ramify, and is lined by a very thin and delicate layer of the same tissue,

FIG. 35.

Lacunæ of *Osseous Substance*, magnified 500 diameters.—*a*, central cavity; *b*, its ramifications.

to which the term 'endosteum' is applied. This also is freely supplied with small vessels derived from the nutrient artery or arteries of the bone. From both the external and internal membranes numerous small bloodvessels penetrate the bone, occupying a series of canals that were first described by Clopton Havers, and have been named after him the Haversian canals. These, for the most part, run parallel to the central cavity, communicating, however, with one another by frequent transverse branches, so that the whole system forms an irregular network, and pervades every part of the solid texture (Fig. 36). The diameter of the Haversian canals varies from 1-2500th to 1-200th of an inch or more; their average diameter may be stated at about 1-500th of an inch. The Arteries and Veins usually occupy separate channels, and those enclosing the latter are, in some instances, as in the diploë of the flat bones of the skull, of extraordinary amplitude. In transverse sections the longitudinally running canals appear as circular spaces surrounded by from five to ten or more concentric lines named 'Haversian lamellæ.' Between the lamellæ the lacunæ are seen as dark, white, or open spaces, according to the mode of preparation and illumination (Fig. 37). Besides the lamellæ just mentioned others are seen which run parallel to the medullary cavity, and to the external surface of the bone, and have hence been named 'perimedullary' and 'peripheric' systems of lamellæ. Lastly, a few lamellæ are seen which are not conformable to either of these systems, but occupy their interspaces. Such 'intermediary' lamellæ are the remains of old Haversian systems which have been gradually removed by absorption. The lamellæ form the proper substance of the bone, being composed of ossein impregnated with calcareous salts. If the salts be removed by maceration in acid the lamellæ present a well-marked fibrous structure, the fibres being transparent and decussating with each other to form an extremely delicate trellis-work. The outermost or peripheric lamellæ are often bolted together by perforating fasciculi of fibres, partly white connective tissue, and partly elastic tissue, apparently continuous with the deep surface of the periosteum. Each lamella presents a thinner transparent and homogeneous zone, and a broader, darker, and more granular zone. The lacunæ are situated in the transparent zone.* The dark zone

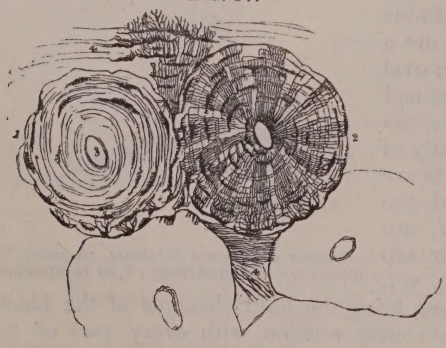
Fig. 37.

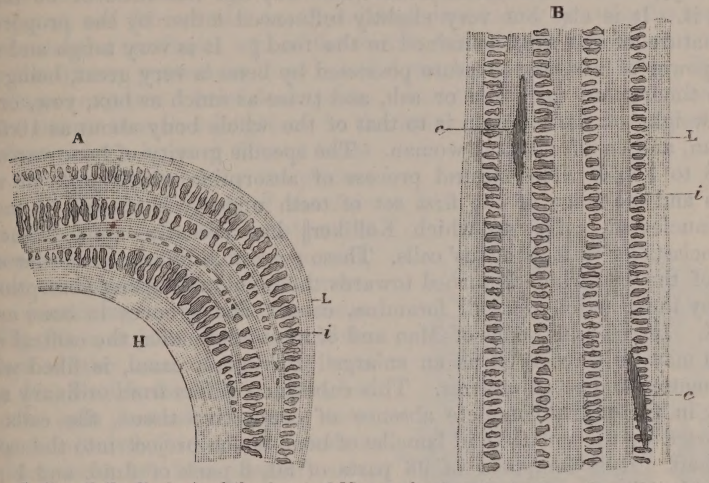


Minute structure of *Bone*, as shown in a section cut transversely to the direction of the Haversian canals:—1, one of the Haversian canals surrounded by its concentric lamellæ: the lacunæ are seen between the lamellæ, but the radiating tubuli are omitted; 2, an Haversian canal with its concentric laminæ, lacunæ, and radiating tubuli; 3, the area of one of the canals; 4, 4, intervening lamellæ; between these lamellæ at the upper part of the figure, several very long lacunæ with their tubuli are seen. In the lower part of the figure the outlines of two other canals are given, in order to show their form and mode of arrangement in the entire bone.

* Sharpey, "Introduction to Quain's Anatomy," 7th Edit. p. xcvi.; Schäfer in idem, 8th Edit. p. 86; and "Quart. Journ. of Mic. Sci.," April, 1878, p. 132.

shows a multitude of short bright lines running radially across it, with dark angular particles between them (Fig. 38). It is not easy to define the limits of a lamella. Sharpey includes both a light and a dark zone in a single lamella, and considers the dark spots to be produced by the cut-ends of the reticulating fibres of which the lamellæ are composed. Schäfer, after com-

Fig. 38.



Section of the diaphysis of the femur of Man, made when the bone was dry and kept in balsam just sufficiently melted to enter into and obliterate the lacunæ.—A, transverse section; B, longitudinal section; H, Haversian canal; L, homogeneous lamellæ; *i*, striated lamellæ; *c*, bone corpuscle. 600 diam.

paring osseous with corneal tissue, defines a lamella as a layer of reticulating fibres covered on both surfaces by a homogeneous substance which extends between the fibres, the plane of separation between two lamellæ being indicated in the fully-formed bone by the presence of flattened lacunæ. The decussating fibres of Sharpey he considers to be the persistent osteogenic fibres. A somewhat different explanation of the same appearances is given by Ranvier, who describes the lamellæ as being alternately clear, or homogeneous and dark, or striated (Fig. 38). He considers the striated lamellæ to be composed of minute connecting rods or bridges with sinuous borders, which extend from one homogeneous lamella to another. This structure, he points out, is apparent both in longitudinal and in transverse sections. If a bone be burnt the organic material that enters into its composition is destroyed, whilst if it be exposed to the action of dilute acid the whole of the salts may be removed, leaving it in a soft and flexible state. In both instances, however, the form of the bone is perfectly preserved, showing how intimate must be the connection between the organic and inorganic constituents. The spongy flat bones contain from 12 to 30 per cent. of water, the compact tissue from 3 to 7 per cent. The chemical analysis of dried bone shows that it consists of from 30 to 34 per cent. of animal matter, which on boiling yields gelatine, and from 66 to 70 per cent. of mineral matter, of which about 57 parts are composed of calcium phosphate, 8 parts of calcium carbonate, 1 part of calcium fluoride, and 1 part of magnesium phosphate.* The degree of hardness of bone does not altogether depend, as shown by the experiments of Dr. Stark,† on the proportion of

* For further details, and for the per-centage composition of the Ashes of Bones and Teeth, see Aeby, "Centralblatt," 1871, p 561; 1873, p. 97.

† "Edinburgh Medical and Surgical Journal," April, 1845.

mineral deposit they may contain; for the flexible, semi-transparent, easily-divided bones of fish contain as large a proportion of earthy matter as the ivory-like leg bones of the deer or sheep. As a general rule, the bones of the extremities contain more calcium carbonate and phosphate than those of the trunk, and the larger long bones more than the smaller ones.* There is no difference in the composition of the corresponding bones of the two sides of the body,† and within certain limits (20—80) age has little or no influence upon it. It is also but very slightly influenced either by the proportion or the nature of the salts contained in the food.‡ It is very tough and elastic. The power of resisting pressure possessed by bone is very great, being nearly three times more than elm or ash, and twice as much as box, yew, or oak.§ The weight of the skeleton is to that of the whole body about as 10·5 : 100 in man, and as 8·5 : 100 in woman. The specific gravity of bone varies from 1·898 to 1·964. The natural process of absorption which parts of various bones and the fangs of the first set of teeth undergo is effected by means of multinucleated cells, to which Kölliker‖ has recently applied the term 'osteoclasts' or 'osteophagous' cells. These present a fimbriated border on that part of the cell which is turned towards the bone undergoing absorption, and it is by their action that all foramina, canals, and grooves in bone are produced. In the long bones of Man and of most Mammalia, the central cavity, which may be considered as an enlarged Haversian canal, is filled with the fatty matter known as *marrow*. This substance differs from ordinary adipose tissue in the nearly complete absence of connective tissue, the cells being supported by the spiculæ and lamellæ of bone which project into the cavity of the shaft. It is composed of 96 parts of fat, 3 parts of fluid, and 1 part of connective tissue. It has been shown to contain lymphoid corpuscles which have no nucleus, but are capable of performing amœboid movements, and are sometimes named 'medullary-' or 'medullo-cells.' With these are large spheroidal cells, presenting one or more nodular or tuberculated nuclei,¶ and large cells with many nuclei.** Although Neumann†† and Bizzozero‡‡ have observed some lymphoid corpuscles in bone which have a reddish tinge, and possess a nucleus, the observations of Hayem§§ do not support the view that these bodies are in process of development into red blood corpuscles, or that the cancellous tissue of bones is an hæmatopoietic organ. Ranvier even‖‖ thinks the coloration of these cells is due to yellowish or brownish granulations, which are the remains of red blood corpuscles that have undergone disintegration, and are in process of removal. In the cancellous tissue forming the expanded extremities of the long bones, and in the bodies of the vertebræ and of the carpal and tarsal bones, a peculiar reddish fluid is found, to which the term marrow has incorrectly been applied, since it contains only a trace of fat. Its per-centage composition is—water 75 parts; albumin, fibrin, and salts, 25 parts. Bones are but feebly supplied with sensibility. A few small nerves may, however,

* Fossil bones sometimes contain a very large amount of Calcium fluoride. Lassaigne, for example, found 15 per cent. in a tooth of the Anoplotherium.

be seen to enter the shafts of the long bones with their nutritious arteries, and to be distributed in the endosteum.

51. The development of bone from cartilage, or *Intra-cartilaginous process of ossification*, is not a metamorphosis, but a process of substitution, in which four distinct stages may be recognised. In the first stage hyaline cartilage is formed; in the second, it becomes calcified; in the third, decalcification occurs with absorption of the tissue, the cartilage-cells opening into each other to form large spaces, and the vascular perichondrium penetrating or eating its way into the non-vascular cartilage; and in the fourth, 'osteoblasts' appear, and coincidently the true or permanent bone is laid down in successive layers. Each of these stages requires a brief description. Just before the process of ossification commences in such a long bone as the femur, it is found to consist of cartilage invested by a layer of fibrous tissue which subsequently becomes the periosteum. In the central part of the cartilage when the ossification is about to commence the capsules increase in size, and are completely filled with protoplasm containing a vesicular nucleus. (See Fig. 39, *a*, and the central part of the cartilage of the head of the long bone in Fig. 40.) Proliferation takes place, but the new cells instead of being irregularly distributed through the matrix form long rows (*a*) like piles of coin, arranged perpendicularly to the ossifying point, and becoming larger as they approximate it. The cartilage now becomes softer, and begins to be penetrated by processes of the periosteum carrying bloodvessels the portions of cartilage intervening beween the rows of cells becoming impregnated with earthy salts in the form of minute granulations. When this deposit or infiltration has taken place absorption commences and the cavities occupied by the cartilage-cells open into one another, the newly-formed larger spaces presenting in their festooned borders traces of their mode of origin. The cartilage-cells have by this time disappeared, and replacing them—but whether as their descendants, or as newcomers introduced with the periosteal vessels is unknown—are small polygonal granular corpuscles (Fig. 39, *c*), capable of performing amœboid movements. The mode of formation of the lacunæ is not certainly known. These bodies, named 'osteoblasts' by Gegenbaur, appear to play an important part in the further process of ossification. They multiply and form a continuous investment to the inner surface of the medullary cavities, and around and beneath them the first lamella of true bone is developed. The newly-formed bone, which is thicker as it is more remote from the cartilage, at length encloses some of the osteoblasts, which probably become the bone corpuscles, occupying the lacunæ of the mature bone (Fig. 39, *p*), but as the osteoblasts that are buried in the newly-deposited bony lamellæ

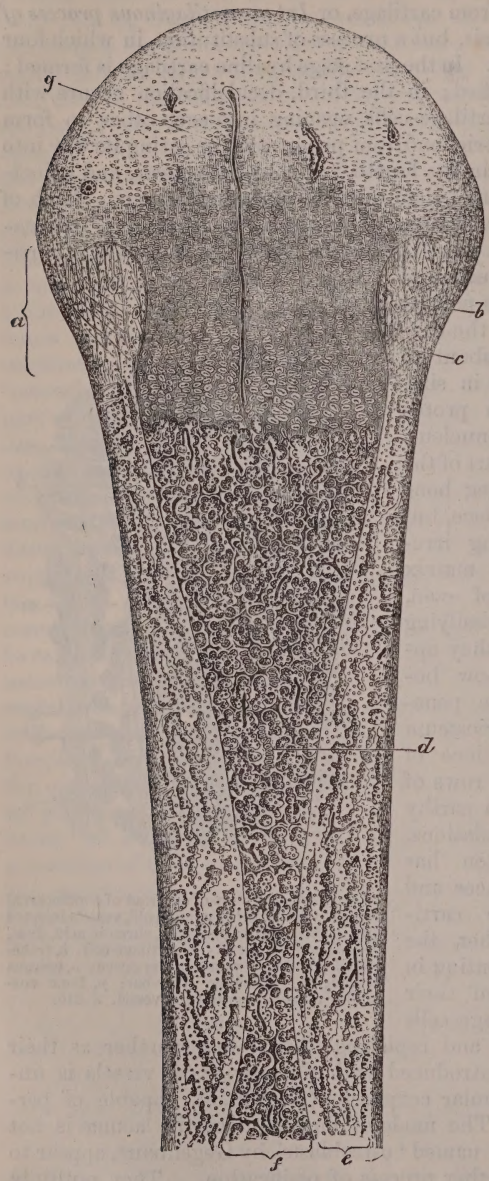
Fig. 40.



present in many instances a stellate form, it is reasonable to think that they constitute the lacunæ. The canaliculi, it is suggested by Ranvier, are spaces or fissures left between two festooned borders of bone, as this gradually advances upon the protoplasm of the osteoblast. The primary osseous lamellæ are deposited on the partially absorbed and partly calcified cartilaginous trabeculæ, which run for the most part parallel to the axis of the bone, and have been named 'directing trabeculæ' by Ranvier.* The central cells remain as the medulla.

52. Ossification, instead of taking place in cartilage, may occur in connective tissue, and to this form the term 'intra-membranous' is applied to distinguish it from the 'intra-cartilaginous' form, which has just been described. It is best seen in the flat bones forming the vault of the cranium, but is also the mode in which the long bones increase in girth. In such a bone

Section through the middle of the humerus of a fœtal sheep. The entire bone was about one inch long—*f*, the part of the shaft which was primarily ossified in cartilage; what remains of the primary bone is represented dark and enveloped by the clearer secondary deposit. The areolæ of this bone are occupied by osteoblasts, with bloodvessels variously cut and represented as dark lines. One long straight vessel, *g*, passes in advance of the line of ossification, far into the cartilaginous head, most of the others loop round close to the cartilage. At one or two places in the older parts of the bone (*d*) elongated groups of cartilage-cells may still be seen, which have hitherto escaped absorption. The part of the bone that has been ossified in membrane, that is to say, in the osteoblastic tissue under the periosteum, is seen at *e*. It is well marked off from the central portion, and is bounded peripherally by a jagged edge, the projections of which are indistinctly seen to be prolonged by branches of osteogenic fibres. A row of osteoblasts covers the superficial layer of the bone. The subperiosteal layer is prolonged above into the thickenlng, *a*, which lies in a groove termed by Ranvier the '*encoche d'ossification*,' and which encroaches upon the cartilage of the head of the bone. In this are seen amongst numerous osteoblasts and a few bloodvessels the straight longitudinal osteogenic fibres, *b*, and some other fibres, *c*, crossing their direction and probably representing the perforating fibres of Sharpey. After Schäfer, partly diagrammatic, magnified about 30 diameters.

* Dr. Ogston remarks that in bone formed from cartilage the chief trabeculæ run at right angles to the plane of the bone surface, whilst in periosteal cartilage they run parallel to the surface, or have no definite direction. ("Journal of Anat. and Phys.," vol. xii. p. 505.)

as the parietal, a deposit of calcareous matter takes place at one point and forms a centre, from which irregular pointed processes radiate into the adjoining connective tissue. Schäfer* describes the spiculæ as terminating in fasciculi of nearly straight stiff-looking osteogenic fibres, between which lie numerous osteoblasts. The calcareous deposit gradually extends into the fibres and intermediate osteogenic substance, and forms the first lamella of the new bone. New osteogenic fibres shoot out from numerous points, and interlacing form a layer, in which again fresh osteoblasts and osteogenic substance appear, with deposit of calcareous matter; and thus a succession of lamellæ are developed by which the bone is thickened, larger channels being left, constituting the Haversian canals, and occupied by vessels and smaller spaces which are the lacunæ. The subperiosteal ossification of the long bones is the same as that of the membrane bones of the skull. The calcareous deposit occurs in the deeper part of the periosteal membrane, and fresh layers are constantly being added by which the girth of the bone is increased. At either end of the shaft the periosteal bone is prolonged for a little distance over the surface of the cartilage, so that the formation of the periosteal membrane bone always slightly precedes the extension of the cartilage bone within. This advanced part of the ossifying cartilage occupies a groove on the surface of the cartilage (as shown in Fig. 40), and is composed of osteoblasts and straight tapering fibres, or osteogenic fibres (*b*), which become the reticulating fibres of the perfect bone; and they are crossed by others (*c*), which probably subsequently become the perforating fibres of Sharpey. Even after the completion of the bone, interstitial changes are continually taking place in its substance, as in that of the softer tissues, old Haversian systems being partially, or entirely removed by absorption, and new ones being developed in their place. And it is to the persistence of portions of these older Haversian systems that the intermediary lamellæ are due. The clavicle and lower jaw are the first bones to ossify, their osseous centres or points of ossification appearing at the close of the first month of fœtal life. Increase in the length of a bone—as may be shown in experiments made by feeding an animal with madder, the newly-formed bone being deeply tinged—takes place almost entirely between the epiphyses and the shaft; but probably also results in part from the interstitial deposition of new material;† increase in girth, by ossification immediately beneath the periosteum; absorption from within and deposition from without going on continually. The former takes place by intra-cartilaginous or '*endosteal*,' the latter by intra-membranous or '*ectosteal*' ossification.

53. Teeth.—As soon as solid food is introduced into the mouth it is divided and comminuted by the Teeth. Partly in accordance with the general fact that epithelial growths die and are cast off to be replaced by others formed beneath them, but chiefly to allow for that enlargement of the jaws which occurs in the passage from infancy to adult age, two sets of these organs are developed—the first, temporary or milk teeth, which last up to the seventh or eighth year, are 20, the second, or permanent set, are 32 in number. Both are firmly embedded in sockets or alveoli of the upper and lower jaws. The front or incisive teeth (8 in number) are, as their name implies, provided with a cutting edge for the prehension and division of morsels of food of appropriate size for mastication. The sharp-pointed canines (4 in number) pierce and cut the firmer and tougher constituents of our

* "Quart. Journ. of Microscop. Sci.," 1878, p. 139, and Pl. viii. Fig. 2.

† For arguments for and against the latter point see "Wolff. Cbl.," 1869, p. 849; 1870, p. 641; Volkmann in "Centralblatt," 1870, p. 129; Lieberkühn, "Centralblatt," 1872, p. 420; Ranvier, "Comptes Rendus," 1873, t. 77, p. 1105.

ordinary aliment, whilst the bicuspids (8) and the molars (12) triturate and bruise the food, till, with the aid of the saliva, it is reduced to the consistence of pulp; it is then fitted for deglutition. Every tooth consists of a crown, a neck, and one or more fangs (Fig. 41), and in all teeth three structures are found—the dentine, which gives the general form and size to the tooth; the enamel, which caps the crown; and the crusta petrosa, which invests the fang. On examining a thin longitudinal section of a tooth the *dentine* is found, like the shaft of the long bones, to be hollowed out into a pulp-cavity, containing a little connective tissue, with bloodvessels and nerves. These enter by a minute orifice at the extremity of the fang. The dentine which surrounds the pulp-cavity is composed of a matrix, which is traversed by numerous tubuli, that radiate from the pulp-cavity towards the external surface of the tooth, and which pursue a gently undulating course, dividing dichotomously, and sending off minute branches. In dry sections the tubuli, having a diameter of about 1-4500th of an inch, are seen to open into the pulp-cavity by one extremity, and by the other to terminate either by exquisitely fine branches, or in similar cavities in the dentine, or overstepping the limits of this, to end in the enamel, or crusta petrosa. The tubuli are most closely set near the crown of the tooth. In the living state they are occupied by prolongations of the protoplasmic cells which fill the pulp-cavity. These processes are not in direct contact with the matrix, but are invested by sheaths—the dentinal sheaths of Neumann. The *matrix* intervening between the tubuli is clear and homogeneous, and in softened specimens gives evidence of being deposited in lamellæ, concentric

with the pulp-cavity (Sharpey). Near the outer surface of the dentine, and also forming certain arched *contour lines* at the crown of the tooth, is a peculiar modification of the matrix, which appears to be broken up into spaces bounded by globular masses perforated with dentinal tubuli—the so-called interglobular layer. The *enamel* (Fig. 43) is composed of solid

four- or five-sided hexagonal prisms of about the 1-500th of an inch in diameter, arranged vertically to the dentinal surface on which they rest, and firmly adherent to one another. The course of these prisms is generally wavy, and their surfaces, in section, are marked by transverse striæ. Enamel is the hardest of all the tissues of the body, and is about equal to that of the mineral named apatite, which it resembles in hardness, crystalline form, and optical characters. As it possesses neither nerves nor bloodvessels, it is not liable to disease; but if from sudden alterations of temperature or from shocks it becomes fissured, particles of food, and perhaps bacteria and other low organisms, penetrate to the dentine, and cause its decay. Care should therefore be taken to brush the teeth after every meal, and to avoid very hot, cold, or acid food. The *crusta petrosa*, or *cementum*, corresponds in all essential particulars with the bone, possessing its characteristic lacunæ and canaliculi. It is destitute, however, of any lamellar structure. It is thickest at the extremity of the fang, and becomes gradually thinner towards the neck of the tooth, where it terminates. The following are the results of Von Bibra's analysis of the component structures of human teeth:—

Fig. 43.

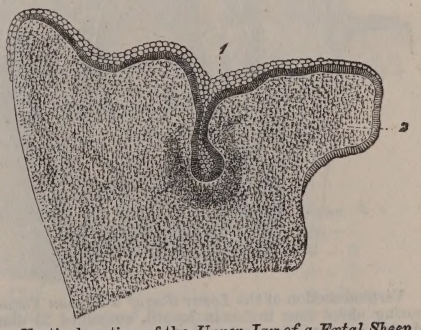
Hoppe-Seyler* assigns the following per-centage composition to the enamel of the new-born child:—$Ca_{10}CO_3,6(PO_4)$, 82·40; $CaCl_2$, 0·23; $MgHPO_4$, 2·37; soluble salts, 0·35; organic substances, 15·59; whilst to the dentine he gives the formula, based on Aeby's analyses, of $Ca_{10}CO_3 6(PO_4)$, 72·06; $MgHPO_4$, 0·75; organic substances, 27·70 = 100·51.

Fig. 44.



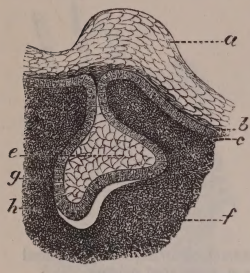
Vertical section of the *Upper Jaw of a Fœtal Sheep*, about 2 inches long, showing the enamel germ, with the semilunar rudiments of the dentine germ and dental sac in transverse section. 1, Dental groove; 2, Palatal process, magnified 50 diam.

In tracing the *development* of the teeth they are found to be essentially dermal structures, which have undergone calcification, the epithelium forming the enamel, and the mucous tissue the dentine and cement. At the sixth week of fœtal life a deep narrow groove may be perceived in the upper jaw of the human embryo, between the lip and the rudimentary palate. This is speedily divided into two by a ridge, which afterwards becomes the external alveolar process; and it is in the inner groove, which is termed the *primitive dental groove*, and is formed

* "Physiolog. Chemie," 1878, p. 182.

exclusively by a depression of the Malpighian layer, that the germs of the teeth subsequently appear. The groove is at first completely covered as well as filled with the thickened epithelium of the oral cavity, so that on a surface view it is scarcely perceptible. From the bottom of the dental groove a narrow process of the oral epithelium dips into the subjacent mucous tissue, presenting on section the form of a short tubular gland (Fig. 44), but really constituting an epithelial fold along the whole length of the jaw. As this fold deepens and enlarges a projection of the mucous tissue takes place in the opposite direction (Fig. 45, *f*, 46, 5). This projection or papilla is the *tooth germ*. By its growth it assumes the form of a club-shaped mass, and the enamel organ invests it like a cap. The first formation of the dentine is effected by cells, termed *odontoblasts*, which lie in the delicate connective tissue, near the surface of the papilla. The odontoblasts arrange themselves vertically to the surface, and each sends forth a process towards the enamel organ (Fig. 47 *a*), around which a dentinal tubule is secreted. They present occasional divisions.

Fig. 45.



a, Epithelium.
b, Younger layer of the Epithelium.
c, Inferior layer of the Epithelium.
e, Enamel organ.
f, Dentine germ or papilla.
g and *h*, Inner and outer layers of the sacculus that is about to form.

Between the papilla or tooth germ and the connective tissue forming the wall of the sacculus is seen a spongy tissue (3) composed of cells, which forms the *enamel organ*. The innermost layer of cells, which are in immediate contact with the papilla, are columnar and regularly hexagonal in section. Their extremities are destitute of a cell-wall, though elsewhere it is well defined. Near the base of the papilla the cells become more cubical, and are reflected at its base upon the inner surface of the wall of the sacculus. The polygonal cells intervening between these two layers become stellate and anastomose with each other, the interspaces being filled with a gelatinous substance, which appears to form a kind of pabulum for the growth of the columnar enamel cells. At all events, it undergoes atrophy, so that the outer and inner epithelial layers come into close apposition; and in teeth examined just at the period of eruption a membrane can be detached from the enamel, composed of one or more layers of very flat epithelial cells, which Waldeyer entertains no doubt represent the cuticle, with more or less of the stratum intermedium or rete mucosum. The enamel itself proceeds from the

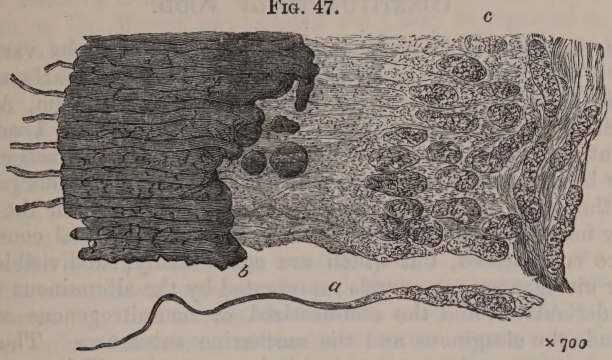
The dental sacculus will be observed to present a number of fine papillæ opposite the dental papillæ.

direct calcification of the long columnar cells, the deposition of the calcareous salts taking place with tolerable uniformity in their outer ends. When the calcification has proceeded to a certain extent, the calcified part may be raised

Fig. 47.



Thin section of the inner portion of the *Dentine*, and of the surface of the Pulp, of an adult Incisor Tooth.—*a*, portion in which calcification is complete, showing separate globular masses at the line of junction with the uncalcified substance, *b*; at *c*, odontoblasts.

in the form of a membrane (Raschkow's 'membrana preformativa'), from the subjacent softer tissue; and thus, as Huxley first demonstrated, the enamel is a petrified epithelium. The formation of the *cement* is identical with the process of intra-membranous ossification in bone. The matrix of the cement is the loose mucous connective tissue of the dental alveoli immediately surrounding the teeth.* As early as the fifth month, before the calcification of the primitive pulps commences, a provision is made for the production of the 'permanent' teeth, the capsules of which originate in buds or offsets from the upper part of the capsules of the 'temporary' or milk teeth. These offsets are at first in the condition of open follicles communicating with the cavity of the primitive tooth; but they are gradually closed in, and detached altogether from the capsules of the milk teeth forming the *reserve sacs*. The three permanent molars, which are superadded in the adult to the milk teeth of the infant, are produced by a precisely similar process of budding from the reserve sac detached from that of the last milk molar.

The following are the principal dates connected with the development and eruption of the teeth:—

Temporary or deciduous teeth.		Permanent teeth.
Period of formation of papilla.	Period of eruption.	Period of eruption.
Week of intra-uterine life.	Month after birth.	Years.

CHAPTER IV.

CHEMICAL COMPOSITION OF THE BODY AND OF THE CHIEF CONSTITUENTS OF FOOD.

54. The elements which enter into the composition of the various fluids and solids of the body are Oxygen, Hydrogen, Nitrogen, Carbon, Sulphur, Phosphorus, Chlorine, Fluorine, Potassium, Sodium, Lithium, Aluminium, Calcium, Silicon, Magnesium, Manganese, Copper, and Iron. Lead is occasionally, but perhaps only accidentally, present.* The combinations of these elementary bodies are divisible into two great groups: the Inorganic represented by the saline constituents, in which they are united for the most part in a binary manner, and the Organic, in which the chemical constitution is much more complicated, but which are again easily subdivisible into the azotized or nitrogenous compounds represented by the albuminous substances and their derivatives, and the non-azotized or non-nitrogenous compounds, which include the oleaginous and the saccharine substances. The inorganic compounds are commonly associated with the organic in sufficient quantities to maintain the body in health, if the food be sufficiently varied, though in one or two instances—as in those of the use of water and of common salt—an additional supply is taken in the pure state. The organic group is primarily and entirely derived from Plants, the office of which is to produce, from the surrounding air, water, and soil, the complex materials of which the bodies of animals are constructed. The inorganic compounds undergo comparatively little change in passing through the body, but the organic—and especially those belonging to the azotized or albuminous type, which have a complicated constitution, their molecules being larger and containing many atoms held together by comparatively feeble affinity—are correspondingly liable to break down under the influence of disintegrating causes, and by their oxidation to liberate the various forms of force which the animal body exhibits. If, for instance, we follow the changes undergone by the albuminous group we shall find that they no sooner enter the stomach than they are placed under conditions—namely, warmth and moisture—that are particularly favourable to decomposition. The peculiar properties of the gastric juice, however, retard and, at the same time, modify the changes they would otherwise undergo. By rendering them soluble it enables them to be absorbed into the blood where they are exposed to the action of oxygen, in a very active state, dissolved in an alkaline fluid. A portion is probably immediately applied to the maintenance and reconstruction of the tissues, and to the formation of the albuminoid constituents of the various secretions, which, in the form of Mucin, Collagen, Spermatin, &c., may be regarded as the immediate derivatives of albumin, whilst a part remains in solution in the blood, and forms a reserve store. Both portions alike—that which forms part of the tissues, and that which forms part of the blood—sooner or later unite with oxygen, and appear to break up into two groups of compounds, the azotized and the non-azotized. The former include such substances as Leucin, Glycin, and Taurin; the Biliary and Urinary acids, Kreatin, Kreatinin, and Urea; and the nitrogenous pigmentary substances. The latter—or non-nitrogenous group—are divisible into those which contain less oxygen than the albuminous compounds, as the fats; or more oxygen, as the carbo-hydrates, glycogen, milk, sugar, and the like. The ultimate results of the further oxidation of

* See Blasius, "Zeits. f. Rat. Med.," Band xxvi. p. 250; and Lossen, "Journal f. Chemie," 1866, p. 460.

both classes of compounds are carbonic acid and water.* The fats and carbohydrates ingested into the stomach, after some preparatory processes, are absorbed into the blood, and undergo the same changes as the corresponding compounds resulting from the breaking up of albumin and its allies. The tissues again, as Dr. Marcet has pointed out,† may be regarded as formed of three different classes of substances—namely, those which constitute the mature or functionally active tissue, and are characterized by being insoluble in water; next, those on their way to form the living tissue—which are soluble in water but of colloidal nature, *i.e.*, incapable of diffusion; and, finally, those which, having performed their function, are effete, and are on the road to be eliminated. These are soluble in water and are crystalloid. Considerable practical difficulty, however, exists in determining whether a particular substance belongs to one class or the other, and in the following account of the proximate principles entering into the composition of the body, we shall first describe the albuminous compounds and their derivatives; secondly, the hydro-carbonaceous; and thirdly, the mineral compounds, following as far as possible that order of descent from the higher to the lower planes of complexity of constitution which experiment and observation render probable.

55. Albuminous Compounds.‡—The albuminous compounds which enter so largely into the composition of the bodies of animals are entirely derived from plants. These yield them to the Herbivora, which are again consumed by the Carnivora. They all contain Carbon, Hydrogen, Nitrogen, and Oxygen, and Sulphur is usually, but not invariably, present. Phosphorus, though often considered to enter into their composition, is now believed to result from contamination with mineral phosphates or with lecithin.§ The grouping of the atoms is so complex that it is difficult to represent it by any rational formula. That of Conglutin obtained from almonds has been given as C_5H_5NO; of Legumin from peas, as $C_{33}H_{54}N_{10}O_{11}$; and of the Fibrin of maize, as $C_{37}H_{59}N_{10}O_{11}$.‖ A knowledge of their per-centage composition is more easily attained, and the subjoined Table¶ will show the close similarity in the composition of those that have been most carefully examined. All the forms of albumin are very unstable, and not only easily decompose themselves, but in decomposing act as excitors of fermentation in other bodies. Most of them exist in two states—a soluble, and an insoluble. The former may be obtained by evaporating the fluids in which they are contained below 100° C. to dryness, when the albuminous substance appears as an amorphous semi-

* The successive steps may be traced, perhaps, most distinctly in the case of guanin ($C_5H_5N_5O$), which is a constituent of the pancreas, through hypoxanthin ($C_5H_4N_4O$) and xanthin ($C_5H_4N_4O$) to uric acid ($C_5H_4N_4O_3$); uric acid again, when acted on by oxidizing agents, yielding urea (CH_4N_2O), allantoin ($C_4H_6N_4O_3$), oxalic acid ($C_2H_2O_4$)$_2$, and carbonic acid (CO_2).

† "An Experimental Enquiry into the Nutrition of the Animal Tissue," 1874.

‡ The best complete accounts of the albuminous compounds are to be found in Von Gorup Besanez, "Lehrbuch der physiologischen Chemie," 1874; Karl Hofmann, "Lehrbuch der Zoochemie," 1879; Hoppe-Seyler, "Physiologische Chemie," 1878; and Kingzett, "Animal Chemistry," 1878; but many scattered papers appear in Pflüger's "Archiv," and the "Zeitschrift f. Chemie," 1876, 1877, and 1878. See also Brunton and Power, "St. Bartholomew's Hospital Reports," vol. xiii. p. 283.

transparent yellowish material, resembling gum arabic, free from taste and smell, neutral to test-paper, and with the exception of Hæmoglobin, quite destitute of any tendency to crystallize. The insoluble form is obtained by heat or by precipitation with various chemical reagents, and forms whitish flocculent masses, which present a granular aspect under the microscope. The albuminous compounds belong to the group of Colloids, founded by Professor Graham, which possess an extremely low power of diffusion through animal membranes. To this peculiarity their feeble taste may in all probability be attributed. They have little or no smell. They dissolve in concentrated acetic and phosphoric acids, and with partial decomposition in caustic alkalies. They are precipitated by alcohol, ether, tannic acid, corrosive sublimate, and most of the mineral acids. On the application of nitric acid they become yellow; concentrated boiling nitric acid dissolves them, forming a yellowish solution which becomes orange on the addition of ammonia (xanthoproteic test); concentrated hydrochloric acid dissolves them, the solution assuming a blue colour. They are precipitated by potassium ferrocyanide. Solution of iodine stains them of a yellow colour, and they all become red at 212° F. when acted on by Millon's reagent, which consists of a solution of the proto- and per-nitrate of mercury. Sulphuric acid holding molybdic acid in solution stains them a dark blue (Frohde's reaction), and when treated with sugar and sulphuric acid under the microscope they give a beautiful violet colour (Schultze's reaction). Von Gorup Besanez* observes that when acted on by powerful oxidizing agents, the albuminous compounds yield formic, acetic, propionic, butyric, valerianic, caproic, and benzoic acids, the aldehydes of these acids, ammonia, and volatile bases; whilst by the action of acids, alkalies, and during putrefaction, they give rise to volatile fatty acids, leucin, tyrosin, glycin, ammonia, volatile bases, sulphide of ammonium and indol, a volatile crystallizable substance having the odour of fæces. In health no albumin is found in the bile, urine, sweat, or tears, though many of the products of the disintegration of albuminous substances can be extracted from those parts of the body, as the glands, in which active processes of metamorphosis are taking place. It is reasonable to suppose, therefore, that the successive stages undergone by the albuminous substances within the body are essentially similar to those through which they pass, when acted on by chemical agents without the body. The aqueous solutions of albumin rotate the plane of polarization to the left.

The albuminous compounds, as the following Table taken from the same author will show, are widely distributed through the body, and in fact may almost be said to be everywhere present.

In 1000 parts of—

Fluids	are of albumin	Tissues	are of albumin

Blood, and Peptones in the section on Gastric Digestion, the chief albuminous compounds will be considered in the following order :—

Albumins	Egg albumin Serum albumin Muscle albumin Acid albumin Alkali albumin Casein
Globulins	Vegetable globulin Vegetable myosin Serum globulin.
Vitellins	Vegetable vitellin Animal vitellin

Ferments

Derivatives of albumin.

Egg Albumin—Ovalbumin—*Albumen—White of Egg.*—This Albumin is contained in meshes formed by a number of fine intersecting fibres. On whipping the white with water the albumin dissolves and the fibres are slowly deposited. The solution forms an opalescent, very slightly alkaline fluid, rotating the plane of polarization 35°·5 to the left, and coagulating completely at 75° C. (167° F.). There appear to be two different forms or kinds of albumin in the white of the egg of the bird—one coagulating at 63° C. (146° F.), and rotating the plane of polarized light $-43°$; the other coagulating at about 74° C. (165° F.), and rotating the plane $-26°$;* and there are some points of difference between the eggs of different birds. Ordinary white of egg contains about 12 per cent. of dry albumin. If it be dried *in vacuo* at ordinary temperatures, or below 50° C., ovalbumin may be heated to 100° C. without being rendered insoluble. It may be obtained so pure that it leaves when burnt no perceptible weight of ash.†

Serum Albumin—*Blood Albumin—Serin.*—The blood contains about 7 per cent. of a peculiar form of albumin, which is also found in lymph and chyle, in all serous fluids, and transudates; as in hydrocele fluid, in colostrum, and in very small quantity in the milk (Lactoprotein), in the fluid of the amnios, and is the common form in which albumin appears in the urine in cases of renal and cardiac disease. Its solutions become cloudy at 60° C., and coagulate at 72°—73° C. When pure it is soluble in water, insoluble in alcohol and ether, yet is not precipitated from its watery solution by ether. It is not precipitated by very dilute acids, by the alkaline carbonates, common salt, or platinum cyanide. Its rotatory power is $-56°$. When injected beneath the skin it does not appear in the urine, whilst ovalbumin is quickly eliminated unchanged. The addition of potash or soda converts it into Lieberkühn's alkali-albuminate.

Muscle Albumin—*Myosin.*—Pure myosin may be obtained by allowing the uncoagulated juice of muscle to fall into water. Each drop forms a gelatinous spheroid, and may then be washed with water. Myosin may also be prepared by kneading finely-minced muscle with water till all traces of blood are removed. It is then triturated with a mixture of one part of saturated solution of common salt and two parts of water; the fluid is filtered, and a frag-

* Gautier, "Bull. Soc. Chem.," 1870, t. xiv. p. 177.

† This may be accomplished by desiccation at a low heat; pulverization, digestion with water at 30° C. (86° F.); filtration, precipitation with alcohol, desiccation at 100 °C. (212° F.); and solution in water acidulated with a trace of acetic acid, which may be afterwards removed by dialysis. On final evaporation pure ovalbumin remains.

ment of rock salt added to it. As this dissolves the myosin is precipitated in flocculi, which may be purified from salt by washing with water. Moist myosin thus obtained dissolves easily in 10 per cent. solutions of common salt, but is no longer dissolves in them after desiccation *in vacuo*. The solution in 10 per cent. NaCl coagulates at 55°—60° C. (131°—140° F.). It is converted into syntonin by very dilute solutions of hydrochloric acid, and into alkali-albuminate by the caustic alkalies. It has the power of rapidly decomposing peroxide of hydrogen. Kühne considers that the condition of the muscles termed Rigor mortis is referable to the coagulation of the myosin they contain.

Acid Albumin—*Syntonin.*—Acid albumin is a product of the action of acetic or of strong hydrochloric acid on various forms of albumin. The term Syntonin is especially applied to the substance obtained by the action of dilute hydrochloric acid (1–1000) on myosin, and is synonymous with Meissner's parapeptone. On exact neutralization with sodium carbonate, a gelatinous mass is precipitated, which when purified from fat by ether is soluble in excess of the alkali, and in dilute acids and solutions of the alkaline carbonates, by which it is distinguished from fibrin, coagulated albumin, and amyloid, but not in solution of common salt, by which it is distinguished from the globulins. It is not precipitated by heat. When pure it is white, transparent, and gelatinous. It does not decompose ozone. Suspended in water at a temperature of 85° C. (185° F.) for a few minutes, syntonin undergoes a change, part of it becoming insoluble in water. Its lævo-rotatory power amounts to $-70°$ to $-74°$. Conversion into syntonin is the first change that albuminous substances undergo in gastric digestion.

Alkali-albumin, or Albuminate, is made by adding caustic potash to a solution of seralbumin or ovalbumin, and allowing it to stand for some hours. Its presence is detected by the precipitate which occurs on exact neutralization with an acid unless sodium phosphate be present, which distinguishes it from syntonin. Hoppe-Seyler obtains it by agitating milk with strong caustic soda and ether; removing the ethereal layer, and adding acetic acid to the watery layer, the precipitate is washed with water, cold alcohol, and ether. It contains no sulphur, the absence of which distinguishes it from casein. Its lævo-rotatory power on light is $-55°$. Its solutions are not precipitated on boiling. Its formula is given as $C_{72}H_{112}N_{18}O_{23}S$ (Hofmann). When placed in acid fluids it becomes opaque, and is converted into Brücke's Pseudofibrin. Acid albumin and alkali-albumin are grouped together under the term Protein by Hofmann.

Casein.—Olof Hammarsten* obtains casein by precipitating it from milk with a trace of acetic acid, dissolving it (after washing) in water containing a trace of alkali, filtering to separate the fat, precipitation with acetic acid; and after a repetition of these processes, frequent washing with alcohol and ether. The casein thus obtained has the character of an acid, giving, when moist, a distinct red stain to litmus-paper; dissolving in caustic alkalies, and expelling carbonic acid from the carbonates, whilst it dissolves the bases. It even dissolves calcium phosphate. The precipitate formed in solutions of casein by acids is by some regarded as a combination of the casein with the acid; but Hammarsten finds the whole of the acid may be removed by frequent washing with pure water. Casein varies in its solubility in different acid solutions—much more acetic than hydrochloric acid, for example, being required to precipitate it. The coagulation of casein by a peptic ferment only takes place when the solution contains a sufficient quantity of calcium phosphate or some other salt of calcium. In the act of coagulation casein splits into at least two new albuminous compounds, of which one, by far the most abundant, forms

* "Festschrift," &c., Upsala, 1877; and "Centralblatt," 1878, p. 470.

he cheesy substance precipitating with calcium phosphate, while the other is peptone-like substance which remains dissolved in the cloudy masses. Solutions of perfectly pure casein in caustic soda do not coagulate on the addition of rennet. One part of rennet ferment is capable of coagulating 800,000 parts of casein, and the addition of calcium chloride up to 0·5 per cent. hastens the process in a very remarkable degree. The casein of human milk is not precipitated on the addition of acids.

Globulin.—Under this term Hoppe-Seyler* includes all albuminous substances which are precipitated from their neutral solutions by the addition of a large quantity of water free from carbonic acid gas, and are completely soluble in dilute solutions of common salt and of neutral alkaline salts. When long in contact with water they gradually become insoluble in neutral solutions of common salt of any degree of concentration, and pass first into albuminate,† and subsequently into coagulated albumin (Syntonin). Acids and alkalies appear to produce the same effect with more or less rapidity. The different kinds of globulin are arranged by Weyl‡ into two groups, the animal and the vegetable, the former containing—(1) Vitellin, which is soluble in solutions of common salt of every degree of concentration; and (2) Myosin, fibrinogen and serum globulin or paraglobulin, which are all precipitable from their neutral solutions on the addition of a few crystals of common salt; and the latter containing vegetable vitellin, vegetable myosin, and vegetable casein. All forms of globulin, whether animal or vegetable, when in contact with water, acids, or alkalies, first pass into albuminates, and subsequently into coagulated albumin.

Vegetable Globulin.—This substance constitutes the albuminous basis common to almonds, peas, beans, lentils, and the cereals. Solutions of vegetable globulin in sodium chloride exhibit the same reactions as those of animal globulin and the animal albuminous compounds generally. They are precipitated by HNO_3, by dilute acetic acid, by acetic acid + potassium ferrocyanide, by acetic acid + sodium chloride, &c. They give a red colour with Millon's reagent, a violet colour on boiling with $KHO + CuSO_4$, &c. The coagula are insoluble in dilute acids and alkalies. The very dilute solutions of these bodies in NaCl are only partially precipitated by CO_2. The precipitate thrown down by H_2O from NaCl solutions dissolve at first completely in solutions of neutral alkaline salts, but after a time, if in contact with water, they change into albuminates, and then dissolve only in dilute hydrochloric acid and in one per-cent. solutions of soda. Vegetable globulin dissolved in a one per-cent. solution of Na_2CO_3 solution precipitated by $H_2 + CO_2$ and suspended in water by the addition of a few drops of a one per-cent. Na_2CO_3 solution, presents exactly the same characters as those of—

Vegetable Myosin.—This is a second globulin substance obtained by Weyl from a ten per-cent. salt solution of the albuminous compounds contained in wheat, peas, oats, white mustard, and sweet almonds. Like animal myosin, with which it agrees in all essential features, it coagulates at a temperature of 55°—60° C. (131°—140° F.).

Serum Globulin (*Weyl*)—*Fibrinoplastic substance*—*Fibrin ferment*—*Paraglobulin*—*Serum Casein* (*Kühne* and *Eichwald*)—*Globulin* (*Heynsius*).—This, according to Weyl, is the only globulin substance in the serum of blood. To obtain it pure, serum is diluted with 15 volumes of distilled water, and a few

* "Handbuch der Phys. Chemie," 1870, p. 196.

† The term albuminate here = alkali-albuminate + acid-albuminate = Protein of Soyka and Weyl.

‡ "Zeits. f. Phys. Chem.," Band i., 1878, p. 72.

drops of dilute acetic acid are added till the fluid is rendered neutral; a flocculent precipitate falls. This can be dissolved in a few drops of a ten per-cent solution of common salt, which takes up about 1·8 per cent. of it, and again precipitated by addition of water, and so on till pure. The clear neutral solution of serum globulin coagulates at 75° C. (167° F.). Serum globulin agrees in all its reactions with the myosin of transversely striated muscle, except that it coagulates at 20° C. (66° F.) higher temperature. The fibrinoplastic activity is greatest when it is obtained by precipitation with powdered salt.

Vitellin—*Vegetable Vitellin.*—This substance has been obtained in a crystalline form by Weyl from Brazil nuts, as well as from maize, peas, and other seeds, by the action of ether. It is the purest form of globulin known. Its elementary composition is C 52·43, H 7·12, N 18·1, SO·55, O 21·8, the proportion of nitrogen being thus extremely high. It coagulates at 75° C. (167° F.) when dissolved in a ten per-cent. solution of sodium chloride. Vitellin crystals are doubly refracting, and when long kept in contact with water a kind of Haptogen or precipitation membrane forms on their surface. These crystals correspond to the Aleuron crystals of Hartig.* Vegetable Vitellin agrees in all particulars with Animal Vitellin.

Animal Vitellin.—This is obtained by exhausting the yelk of egg with ether, which removing the coloured oil leaves vitellin with some lecithin and nuclein as a white residuum. This is dissolved in a very small quantity of a ten per-cent. solution of rock salt and precipitated with water, by a repetition of which process it is gradually purified. Its neutral clear solution in ten per-cent. solution of salt coagulates at 75° C. (167° F.). Substances which appear to agree in their reactions with vitellin have been found by Hoppe-Seyler in the chyle,† by Weyl in the amniotic fluid in a case of hydramnion at the seventh month, and by Hoppe-Seyler and Laptschinsky‡ in the lens of the ox.

Ferments, so far as is at present known, are of two kinds,§ the organized, particulate, formed, or insoluble, like yeast; and the unorganized, diffused, unformed, or soluble, like pepsin and ptyalin in the animal body, or diastase in the vegetable. The latter class of ferments are also called by Kühne Enzymes. We are as yet in total ignorance as to the rationale or method of working of ferments, and various theories have from time to time been put forward as to their mode of action. Of these the *contact theory* of Berzelius

* "Bot. Zeit.," 1855, p. 881; 1856, p. 263. "Entwickelungsgeschichte des Pflanzenkeimes," 1858, p. 108.

† See Weyl, loc. cit. p. 75, note.

‡ Pflüger's "Archiv," 1876, Bd. xiii. p. 633.

§ Hoppe-Seyler ("Physiologische Chemie," I. Theil, Berlin, Feb., 1877, pp. 113–122) classifies ferments into the two great divisions of organized (formed) and unorganized (unformed) ferments. The fermentative process he divides into—

I. A change from the anhydrous to the hydrated condition.
   a. The ferment acts like a dilute mineral acid at a boiling temperature: as in
      (1) The conversion of glycogen into dextrin and grape sugar.
      (2) The transformation of cane into grape sugar.
      (3) The change of benzole glucosides into sugar and simpler benzole derivatives.
      (4) The conversion of sulphur holding bodies into sugar, sulphuric acid, and oil of mustard.
   b. Ferments acting like caustic alkalies at a high temperature.
      (1) The conversion of ether, fats, &c., into alcohol and acids.
      (2) The decomposition of amide compounds under the influence of a putrefactive ferment by the taking up of water.
II. Fermentative changes with the transference of oxygen from hydrogen to carbon.
      (1) Lactic acid fermentation.
      (2) Alcoholic fermentation.
      (3) Putrefactive processes.

supposes that the ferments, chiefly the unorganized, possess a catalytic power, where is understood by the word catalytic the act of rearrangement of the molecules of a substance when the cause of the change is not itself changed; or, in other words, where the fermentation proceeds without causing corresponding changes in the ferment. The *mechanical theory* explains the action of ferments by supposing that they are substances whose molecules are in a state of rapid vibration; that these vibrations are communicated to the molecules of the substance in which fermentative changes are produced, but that the vibrations of the molecules in the two bodies being dissonant, those of the fermented body fall down or are rearranged, thereby producing new compounds, and at the same time liberating certain forms of energy. The *physical theory* of Willis and Stahl, advocated by Liebig, explains the phenomena of fermentation by supposing that "yeast, and in general all animal and vegetable matters in a state of putrefaction, will communicate to other bodies the condition of decomposition in which they are themselves placed, and the motion which is given to their own elements by the disturbance of equilibrium is also communicated to the elements of the bodies which come into contact with them."* Lastly, there is the *vitalist* theory, which has of late years received so much support from experiments carried out by Pasteur. This theory takes for granted that there are in the air numberless germs or spores of the lowest forms of plant and animal life; it is the germination of these spores in the fermenting substance which brings about those changes known as fermentative. Turpin sums up this theory in the formula, "Fermentation as effect, and vegetation as cause." As might be supposed, somewhat more is known about the organized than about the unorganized ferments. Taking, as an example of the former class, the yeast plant *Saccharomyces cerevisiæ*—a very low form of plant life—we find that it consists of a number of Plastids, or elementary organisms, aggregated into chains—the so-called Torula chains. These chains are, in the language of Herbert Spencer, feebly-pronounced indications of a secondary aggregate; they are formed by a process of exogenous gemmation. They grow very rapidly, if supplied with sufficient oxygen and proper food, and as they grow they set free large quantities of carbonic acid, whilst any grape-sugar which may be present is converted into alcohol. The growth of this Protophyte, therefore, brings about a certain change in a solution which contains grape-sugar—viz., the conversion of the grape-sugar or dextrose into ethyl alcohol, and it is this change which is known by the name of *alcoholic fermentation*. This fermentation is not dependent entirely upon the growth of the Saccharomyces, or any protophyte nearly allied to it; for the experiments of Pasteur† seem to prove that vegetable cells generally can produce alcohol and carbon dioxide at the expense of sugar; the action, however, is much less energetic than with yeast. In addition to the formation of alcohol and carbon dioxide, minute traces of other substances, such as succinic acid and glycerine, can generally be detected. This alcoholic fermentation is one of the simplest examples of fermentative action; chemically stated, it is roughly as follows: $C_6H_{12}O_6 = 2C_2H_6O + 2CO_2$. Dextrose, under the action of yeast, yields ethyl alcohol and carbon dioxide.

The means whereby this change takes place, and the mode in which it occurs, have given rise to the most diverse speculations. The theories on this subject may be divided into two classes, the chemical and the biological. In both cases the ferment as it grows is supposed to abstract something from the fermenting substance, and it is perhaps, on the whole, best to suppose that the

* Liebig, "Ann. de. Chem. et de Phys.," ser. ii. vol. lxxi. p. 178.
† "Comptes Rendus de l'Acad. de Sci.," vol. lxxv. p. 784, et seq.

phenomenon is fundamentally one belonging to biology and explicable upon biological grounds. In the first place it is to be remarked that the amount of yeast produced during a fermentation bears no relation to the amount of sugar which disappears, but is rather proportional to the amount of oxygen present.* Again, when yeast is deprived of sugar it undergoes a singular change, which appears to be due to its fermenting itself. In this case, as well as experiments with yeast which has been deprived of oxygen, it is found that the ferment action is reduced to a minimum ; but on the addition of a saccharine solution the action gradually increases and becomes stronger. From these and other considerations it appears best to suppose that the yeast contains within itself one of the second class of ferments, or a soluble ferment, and it has been actually found that an active solution of yeast, the so-called yeast-water, may be obtained, which is free from proteids. This yeast-water is rendered inactive by the addition of borax, a salt which has a neutralizing action upon the soluble ferments, though it does not interfere with the organized ferments.†

In the second kind of fermentation, due to the presence of an organized ferment, lactose or milk-sugar is converted into lactic acid. This change is known as *lactic acid fermentation ;* it has been supposed to be due to the presence of small globules formed of short joints, the lactic ferment, and this theory has been lately supported by Professor Lister,‡ who has given to the motionless protophyte, which brings about the change in milk known as souring, the name of Bacterium lactis.

A third organized ferment is that of the Mycoderma aceti, which effects the conversion of alcohol into vinegar—*the acetic fermentation* ; this same change can be brought about by subjecting alcohol to the action of spongy platinum, the great difference being that when platinum is used the alcohol is more readily transformed if it is concentrated, whereas with the Mycoderma the alcohol should not be more than 10 per cent. The action of the protophyte, however, is not simply mechanical, for the oxidizing property is lost above 95° F. and below 50° F.

The Butyric Acid Fermentation, in which lactic acid and all substances capable of undergoing lactic fermentation are made to yield butyric acid, is apparently due to a special form of Bacterium of the genus Vibrio;§ or, according to later researches, to bacillus. It is not yet known whether the alkaline fermentation which urine undergoes is due to an organized ferment,‖ or whether it is caused by the presence within itself of a peculiar soluble ferment which is capable of converting urea into carbonate of ammonium.¶

In considering the organized ferments, it is thus seen that they are divisible into two great groups : in the one fermentation is due to an order of protophytes known as the Saccharomyces, to which yeast belongs; in the other, the changes are brought about by another order of protophytes—the Schizomycetes; or, in simpler language, the fermentation is caused by the yeast-plant and its allies, or by Bacteria, of which there appear to be several forms. Yeast fermentation** requires oxygen in considerable quantities, and it forms products which are not disagreeable to the senses ; on the other hand, Bacteria fermentation does

* Pasteur, "Bullet. Soc. Chem.," 1861, p. 621.

‖ C. Bastian, "Comptes Rendus," lxxxiii. No. 8.
¶ Musculus, "Comptes Rendus," lxxxii. p. 333.

** This appears, however, only to be the case with fresh yeast, for ready-formed yeast can grow in the absence of oxygen, the requisite oxygen being derived not from the sugar, but from albuminoid substances, since unaltered sugar is found in the liquid after the yeast has ceased to grow. When oxygen is excluded, yeast can induce fermentation in pure sugar solutions, but in this case the yeast does not increase. (Watts' "Dict. of Chemistry," vol. viii. part i., Supp. III., 1879, Art. Fermentation.)

not require oxygen, or at least it can obtain oxygen from the fermenting substance, and its products are very disgusting to the sense of smell. Witness many butyric fermentations; it is, in fact, putrefaction. It is very possible that in many artificial fermentations, and in some natural ones, as we have seen, Bacteria play a very great part, and that, too, in cases which are ordinarily supposed to be due to the action of a soluble ferment; though Hoppe-Seyler* states that there is a special ferment in Bacteria and others of the lowest organisms, which produces the processes of decay. This ferment he believes also to be present in the organs of higher animals, and probably also generally in plants. He bases his statement on the fact that the fermenting power is not lost when a watery solution is shaken up with ether and is then allowed to stand, although all living organisms are thereby destroyed. Heating to 53° C. destroys the ferment, which appears to be insoluble in water, or at any rate incapable of diffusion through animal membranes or dialyzing paper.

In the healthy animal body, so far as is at present known, *organized* or *particulate* ferments take no part, except perhaps doubtfully in the pancreas. The secretion of this gland, poured as it is into the alimentary tract, brings about a process of disintegration of proteid materials, which when carried to its furthest extent results in the formation of an unsavoury substance known as Indol. It is the presence of this material which gives to the excrementitious matter of the intestine, and to artificial pancreatic digestions, their peculiarly penetrating and unpleasant odour. Indol is always found to be produced concomitantly with a copious development of Bacteria in artificial digestions with pancreatic infusions; and as Bacteria are known to occur in the alimentary canal,† it is argued‡ that they have some influence in the production of Indol—that is to say, in carrying on the pancreatic digestion of albumins beyond its normal limit. Pathologically, organized ferments are found in the body. The disease known as malignant pustule in Man is caused by the growth of numberless small Bacterioid bodies in the blood. Dr. Cossar Ewart§ has studied the development of the Bacillus anthracis, whose relation to splenic fever was pointed out by Cohn and Koch.‖ Dr. Johnston¶ attributes Summer diarrhœa, such as ordinarily affects infants and adults in hot weather, to the presence in the intestine of Bacterium termo and the spherules of micrococcus which are found in large numbers in the stools and vomit of patients suffering from this disease. The Flacetodezza, or silkworm plague, is similarly due to the presence of Bacteria; whilst it has been put forward by some very competent authorities that syphilis and typhoid variola** are caused by the presence of organized ferments. These considerations, however, must be passed over, as they have already carried us too far from our present subject of ferments; and would lead us into the, at present, hotly-contested territory of contagia viva, or disease germs.††

Let us turn now our attention to the second class of ferments—*the Soluble Ferments.* From a physiological standpoint these ferments are of an even more absorbing interest than are the organized ferments, for they are primarily

†† Parkes' "Practical Hygiene," 5th ed. p. 510.

the means whereby our food is digested, or converted into material fitted for assimilation by the tissues. As yet the nature and mode of action of unorganized ferments is absolutely unknown. We cannot tell whether they are one or many; whether they are all produced from a single substance, or whether each is formed by a peculiar body; whether they are secreted by special cells from the blood, or whether they are manufactured *de novo* in the gland itself; whether they are, after use, cast out of the body, or whether they are absorbed again into the circulatory medium. In dealing with the unorganized ferments it will be advisable to confine ourselves to those which are actually formed in the body. We shall therefore dismiss without further notice the ferment *Diastase*, which is found in malt, converting the starch present in the grain into dextrose or grape-sugar; *emulsin or synaptase*, which transforms amygdalin into oil of bitter almonds, hydrocyanic acid and glucose, and which acts generally upon glucosides; *Myrosin*, which converts potassium myronate into allyl, sulphocyanide, glucose, and potassium bisulphate; and finally, *Erythrozyme*, which splits up the glucosides found in madder-root which possesses the power of inducing alcoholic fermentation in solutions of sugar. In all these cases, as in soluble ferments generally, the process of fermentation is not hindered by the presence of oxygen, even at high pressures, whereas compressed oxygen destroys organized ferments after a longer or shorter time. Borax,* on the other hand, destroys all soluble ferments, whilst it has no effect upon the particulate ferments. By either of these methods, a particulate may be separated from a diffused ferment in any case of doubt. As yet no soluble ferment found in the animal body has been more than approximately isolated; perhaps Brücke's† extract of pepsin obtained by a complicated process, to be presently noticed, was the nearest approach to the isolation of a ferment of this description which has yet been made. This extract was active in the conversion of fibrin into peptone, but was itself free from all trace of proteids; it contained nitrogen. The general method for the approximate isolation of a non-particulate ferment may be thus indicated: the gland or mucous membrane from which the ferment is obtained is finely minced, and is then thrown into a large excess of strong alcohol, where it is allowed to remain for several weeks; by this means the proteids are thoroughly coagulated; the alcohol is then filtered off, and the pieces are dried lightly with filtering-paper, and are then put into concentrated glycerine. The glycerine extract thus obtained is exceedingly active as an amylolytic agent, in many cases with salivary glands, and nearly always so with pancreas. Tested chemically, an extract obtained in this way should give but very slight proteid reactions. Brücke, to obtain the extract already alluded to, exposed the minced mucous membrane of the stomach to a temperature of 95° F. with water containing 5 per cent. phosphoric acid. The extract thus obtained he precipitated with lime-water, and dissolved the precipitate of calcium phosphate in a minimum of dilute hydrogen chloride. He again reprecipitated with lime-water, and again dissolved with dilute hydrogen chloride. The liquid was then shaken up with a solution of cholesterin dissolved in four parts of alcohol to one of ether. The cholesterin which separated and rose to the top was filtered off, was washed with water acidulated with acetic acid, and then with distilled water alone. It carried the pepsin. The moist cholesterin was dissolved in pure ether. The ether was removed, and there remained a watery but very actively peptic solution. From this it is seen that, with some exceptions to be mentioned presently, these diffuse ferments of the animal body are insoluble in ether and alcohol, but are soluble in water, and particularly so in glycerine. The following unorganized ferments have been distinguished in the animal body:—

* Dumas, "Comptes Rendus," vol. lxxv. p. 295.

† Moleschott's "Untersuch.," vi. 1869, p. 479.

I.—Amylolytic or Diastatic ferments—*i. e.*, the ferments which convert starch or amyloids into grape-sugar or dextrose. These are :—

a. Ptyalin, found in the salivary glands, and by Cohnheim in the urine. In man the saliva of both the submaxillary and parotid glands contains this ferment.

b. Amylopsin,* found in the pancreas, and separated by Cohnheim and Danilewski.† This ferment is much more rapid and energetic in its action than ptyalin.

c. A ferment‡ found in the *liver*, which converts glycogen into sugar.

d. A ferment found in the *bile*, which is capable of converting starch into sugar; its action, however, is but of minor importance.

e. A ferment found in the *blood*, which is probably the same as that found in the liver, since it has the same properties.

f. A ferment found in the *gastric and intestinal mucous membrane*§ of the dog and horse.

g. In most animals an amylolytic ferment can be obtained from almost any part of the body.

II.—Proteolytic ferments are those which have a distinctive action upon proteid compounds. They are :—

a. Pepsin, found in the peptic glands of the mucous membrane of the stomach, and by Brücke in the blood, muscles, and urine; like the amylolytic ferment, pepsin is very widely distributed in the body. Its action is one of solution, and it is active only in an acid medium.

b. Trypsin or *Myopsin*‖ is the proteolytic ferment of the pancreas. It converts albumins into peptones, and ultimately into leucin and tyrosin. It is active only in an alkaline medium, and its action is one of corrosion. It appears to be produced in the pancreas under somewhat different circumstances from the amylopsin already mentioned. Trypsin has also been found in the urine.¶ It is active, according to Salkowski, after it has been heated to 160° F.

c. Two ferments found in the saliva—one by Hüfner, which is active in alkaline media only; and a second by Munk** in the mixed human saliva, which is active only in acid solutions.

III.—Inversive ferments which are capable of transforming cane-sugar into dextrose and levulose :—

a. Such a ferment was found by Cl. Bernard in the Succus entericus; it may also possibly act as a proteolytic ferment.

b. A ferment found in the mucin of the stomach. This ferment is analogous to, but quite distinct from, ptyalin.††

c. A ferment obtained by Bertholet from the tissue of the testis; it converts glycerine and mannite into glucose.

IV.—The ferment which is probably contained in the white blood corpuscles, which brings about the union of fibrinogen with fibrinoplastin to form fibrin in blood coagulation (q.v.).

V.—*Ferments with an action on fat* :—

†† Foster, "Physiology," 2nd ed. p. 189.

Steapsin,* a special ferment present in the pancreas which has the power of breaking up fats into glycerine and the corresponding fatty acids.

The emulsifying power which the pancreatic juice exerts upon fats is not due to any special ferment, but is dependent, in all probability, upon the presence of alkali albumin.

A special ferment in the spleen, which is said to split up fats into glycerine and the corresponding fatty acids; the existence of this ferment is somewhat hypothetical.

VI.—A special ferment contained in the gastric juice which has the power of curdling milk, probably by the conversion of the lactose or milk-sugar into lactic acid; when this happens the casein is precipitated.†

In describing the method of isolating unorganized ferments, it was stated that there were certain exceptions in which a ferment could not be obtained by the method there indicated. This is the case with trypsin, the proteolytic ferment of the pancreas; for if the gland be removed from an animal immediately after death, the glycerine extract has no power of digesting fibrin unless it be treated with a dilute acid, such as hydrochloric or acetic. It is thus necessary under ordinary circumstances to keep the pancreas for some hours after death before proceeding to make an extract of it. In the same way, a piece of boiled liver, in which no sugar could be detected, has been found to contain sugar after the lapse of twenty-four hours. Again, certain extracts of pancreas, such as those made from a fasting animal, are found to be inactive towards proteids, whilst extracts of salivary glands are inactive in relation to starch. In each case the addition of dilute hydrogen chloride causes them to become active; so also an inert solution of pepsin becomes active on the addition of hydrochloric acid. Now these results all point to the fact that the ferment, as such, is not present in the gland in an active condition, but that it only becomes capable of exerting its peculiar function after it has undergone some change; in other words, the ferment is produced directly from some other substance. It is this substance to which the name Zymogen (the mother of ferment) is applied as a general term. Assuming that Zymogen really exists, there arises a question as to the relation in which it stands to the various ferments of the body, whether as their common origin, or whether other intermediate substances intervene. In the latter case, which is by some assumed to be true, the intermediate substances have received special names in the case of the stomach and pancreas; thus, the substance producing pepsin is termed Pepsinogen, whilst that which gives rise to trypsin is similarly Trypsinogen. As yet but little is known of these bodies, it being supposed, on theoretical grounds, that Trypsinogen is soluble in glycerine, whilst Pepsinogen is insoluble in the same medium. Neither body has yet been isolated.

It is stated,‡ apparently however upon insufficient evidence, that trypsin ceases to be present, or at any rate ceases to be active, in the pancreatic secretion after extirpation of the spleen. There is as yet no answer to the question whether Zymogen is the common product from which trypsin, pepsin, ptyalin, &c., take their origin; it is known, however, that these, the resultant ferments, are distinct, not only from their mode of action, but also from the fact that trypsin, which probably contains nitrogen in considerable quantity and is proteid in nature, is capable of being digested by pepsin. Of the formation of Zymogen, which appears to be a long and toilsome process, and of its conversion into ferment, if such occur, we know but little.

Derivatives of Albumin.

56. Collagen, Gelatin, or Glutin.—Collagen is pure connective tissue. Gelatin and glutin do not pre-exist in it, but may be obtained by boiling connective tissue, articular fibro-cartilage, or bone with water, especially if this be slightly acidified. The solution gelatinizes, even when gelatin is only present in the proportion of 1 per cent.; many salts, however—as common salt, nitre, and ammonium chloride, as well as dilute acids—prevent solutions of gelatin from setting. Pure gelatin is a colloid and is colourless, transparent, and destitute of taste and smell. Its solutions are precipitated by alcohol and ether, but not by acids, with the exception of tannic acid, which constitutes its most delicate test. It is also precipitated by chlorine water and corrosive sublimate, but not by other salts of mercury, nor by those of silver, copper, lead, or alum, nor by potassium, ferro- or ferricyanide. Solutions of gelatin do not dialyze. They possess a levo-rotatory power which at 25° C. (77° F.) = −130°, and at 40° C. (104° F.) = −123°. Gelatin is soluble in a large quantity of glycerine. The per-centage formula of gelatin is given somewhat differently. Scherer, experimenting with gelatin from tendon, obtained C 50·9, H 7·2, N 18·3, O 23. When exposed to the action of concentrated acids, alkalies, and oxidizing agents, gelatin behaves like the albuminous compounds generally, yielding amongst other products leucin and glycin.

Elastin is the basis of elastic tissue, and may be obtained in a pure state from the ligamentum nuchæ by boiling it successively with alcohol, ether, water, concentrated acetic acid, dilute solution of potash, and hydrochloric acid. When the residue is thoroughly washed it forms a yellowish fibrous mass, still possessing great elasticity, which dissolves in concentrated alkalies and in sulphuric acid, which last decomposes it, giving rise to leucin. With nitric acid it gives the xanthoproteic reaction. Heated on platinum it burns away without leaving any residue. It contains no sulphur. The per-centage formula is C 55·5, H 7·4, N 16·7, O 20·4 (Hofmann).

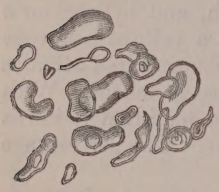
Chondrin is obtained by heating permanent cartilage freed from periosteum, or the cornea of the eye, with water in a Papin's digester at a temperature of 120° C. (248° F.) for three hours, filtering whilst hot, precipitating with acetic acid, washing and removing all traces of fat with alcohol and ether. It forms a hard transparent yellowish mass, insoluble in ether and alcohol, and separating from its hot aqueous solutions, which have a levo-rotatory power, in a gelatinous form. It appears to be a modification of gelatin, from which it differs in being precipitated by acetic acid: the precipitate being soluble in potassium, ferro- and ferricyanide, which distinguishes it from albumin. It is also precipitated by dilute mineral acids and by the salts of alum, iron, lead, silver, and copper, whilst its solutions are only rendered slightly turbid by tannic acid. When boiled with sulphuric acid it yields glycin, but no leucin. It is not as yet accurately ascertained whether gelatin and chondrin pre-exist in the tissues from which they are obtained, or are produced by the act of boiling, for, on the one hand they cannot be obtained by maceration in cold water, whilst, on the other, the action of tannic acid on the tissues seems to be of the same nature as on the solution, and when exerted upon the connective tissues of the skin converts it into leather. Its per-centage composition is C 50, H 6·6, N 14·4, O 20·6. When subjected to the action of hydrochloric acid, or of gastric digestion, chondrin yields a kind of sugar named *Chondroglycose*.

Keratin constitutes the basis of the various horny tissues, as epithelium, epidermis, nails, hoofs, claws, horn, wool, hair, and feathers. It can be obtained from the brain by peptic digestion. It is characterized by swelling

and becoming soft in boiling water, though it neither dissolves in this fluid unless the temperature is much raised by pressure, nor in ether or alcohol. With the exception of hair the tissues in which it is contained are soluble in acetic acid and in alkalies. It is coloured yellow by nitric acid, and under the action of sulphuric acid developes much leucin and tyrosin. The horny tissues in their early state are all composed of soft cells, which subsequently become modified in form, and much firmer in consistence. They contain C H N O and S in proportions that, whilst closely similar to those of the albuminous compounds from which they are derived, have not yet been accurately determined.

Mucin.—A substance possessing in a high degree the power of absorbing water, and swelling up to a gelatinous and sticky mass of semi-fluid consistence which is incapable of dialyzing. No precipitate or coagulation occurs in mucin at a boiling heat, nor is any produced by acetic acid, the mineral acids, or potassium ferrocyanide. It occurs in the body in the mucous fluids, and may be obtained by boiling water from the fœtal connective tissue. It is contained in the fluid of Ranula. Its per-centage composition is given as C 49·5, N 9·6, H 6·7, O 34·2, and it therefore differs from albumin in being free from sulphur, and in containing a smaller amount of carbon and nitrogen. The substance formerly named *Pyin*, and obtained from pus, is probably only a mixture of various albuminous compounds.*

Fig. 48.



Myelin.

Cerebrin.—This substance, the exact composition of which is not known, is obtained from pus-cells and from nerve-tissue by a complicated process. It forms a white light powder destitute of taste and smell, and composed of roundish granules. At 80° C. it reddens, then swells up, and at higher temperatures melts and burns. It is soluble in boiling ether and alcohol. Moist cerebrin, especially if not freed from admixture of lecithin and cholesterin, exhibits the so-called Myelin forms—which are double-edged drops strongly refracting light, and which extend and contract themselves, and perform peristaltic movements.

Protagon, formerly regarded as a constituent of nerve-tissue, appears to be a mixture of cerebrin and lecithin.

Nuclein, $C_{29}H_{49}N_9P_3O_{22}$.—This substance was first obtained by Miescher from the nuclei of pus corpuscles,† and afterwards from the yolk of egg, the spermatozoa of salmon and other fish, and of the bull. Hoppe-Seyler extracted it from yeast, from the cells of a papillomatous tumour, and the bran of wheat; and Plosz separated it from the nuclei of the red corpuscles of birds; traces of it have been found in the liver and in the brain. It may best be obtained by digesting pus corpuscles with warm alcohol, removing the albuminous compounds by peptic digestion and purification with alcohol ether and solution of soda, by which last part is dissolved. On the addition of hydrochloric acid this part precipitates and is washed with alcohol. The remainder is *soluble nuclein*. It dissolves in alkaline fluids, forming pale-yellow solutions, and is precipitated by hydrochloric and acetic acids. It is insoluble in water and in solutions of common salt. In its reactions it resembles Lardacein. That part which does not readily dissolve in solution of soda is *insoluble nuclein*, so called because it dissolves very slowly in caustic alkalies and in strong hydrochloric acid, and not at all in glacial acetic acid, even when heated for hours at 140° C.

Nuclein‡ is not attacked by any of the digestive ferments, and may be

* Hofmann's "Lehrb. d. Zoochemie," p. 8, 1878.

† Hoppe-Seyler's "Med. Chem. Untersuch.," Heft iv. pp. 441, 502.

‡ A. Bókay, "Zeits. f. Phys. Chemie," Band i. p. 157.

egarded in all probability as a constant constituent of the fæces, since it is ontained in the greater number of alimentary substances.

If the recent researches of Morochowetz be correct,* nuclein, mucin, and myloid substance are identical. They all contain phosphorus, though the proportion slightly differs—mucin, for example, containing 2·45 per cent., and myloid substance 3 per cent. Their chemical reactions appear to be identical.†

Carnin, $C_7H_8N_4O_3 + H_2O$.—A base that has been obtained by a complicated process from American meat extract.‡ It forms a white friable mass composed of bitter crystals, easily soluble in boiling water, insoluble in alcohol and ether. Its solution is neutral. When treated with bromine or chlorine, or with hot nitric acid, it forms a salt of Sarkin. It contains the elements of Sarkin and of acetic acid ($C_5H_5N_4O$ and $C_2H_4O_2$), and only differs from theobromine in having one more atom of oxygen. Its physiological value and action are unknown.

Lardacein.—A peculiar form of degeneration, formerly known and described under the name of "amyloid" or "waxy" degeneration, takes place in certain tissues and glands. It appears to be due to a metamorphosis of albumin and the formation of a nitrogenous compound, termed Lardacein. This is best obtained by mincing the affected liver or spleen; removing the vessels as far as possible; extracting with cold water; boiling the residue with water to remove connective tissue in the form of gelatin, and with alcohol and ether to remove cholesterin and fat, and finally with alcohol containing common salt. The mass is subjected to the action of a powerful digestive fluid at 40° C. as long as the filtrate reacts to xanthoproteic and peptone tests. It is then boiled once more with solution of common salt in alcohol, and the dry mass is triturated with water to separate elastic fibres. It is amorphous, friable, insoluble in water, alcohol, ether, diluted hydrochloric or acetic acid. It is not capable of conversion into peptone, and is not liable to putrefaction. It is soluble in moderately concentrated ammonia and in strong hydrochloric acid. Iodine stains it reddish-brown or violet, or even blue. Methylanilin stains it red. Its per-centage composition is C 53·60, H 7, N 15·53, O 22·53, S 1·30.

Aleuron§ is an azotized substance of complex constitution, found in some parts of animals, and even more widely distributed in the vegetable kingdom than starch; it was discovered in 1855 by Hartig. It is found in every part of plants, as in the wood, bark, roots, and seeds. In oleaginous seed it forms the largest and most important part of the perisperm. In order to obtain aleuron, the parts containing it are washed in oil as starch is washed in water; on standing it is deposited from the oil in the form of a fine powder, which is purified by the action of alcohol and ether. Under the microscope it appears in the form of small ovoid or spheroidal grains, varying from $0^{mm}{\cdot}00125$ to $0^{mm}{\cdot}0375$. M. Hartig has applied the term "solitaires" to the large grains found amongst those that occupy a cell, as in Bertholletia and Corylus; and "grains comblants" to those which are so large as to fill a cell by themselves, as in Myrtus and Juglans. Aleuron grains are usually colourless, but may be green (Pistacia), indigo-blue (Matthiola seeds), rose-red (Hibiscus), yellow

* "Petersburger Med. Wochens," No. 10, 1878.

† According to Hake and Kingzett ("Quart. Journ. of Science," Jan., 1877, and "Animal Chemistry," 1878, pp. 278 and 359), the presence of phosphorus in the various published papers on the composition of Nuclein clearly shows the impurity of the preparation, and its contamination with Lecithin. Worm Müller (Pflüger's "Archiv," Band viii. p. 190) also regards it as an impure albuminous substance. (See "Animal Chemistry.")

‡ By Weidel, "Ann. Chem. Pharm.," Band clviii. p. 353.

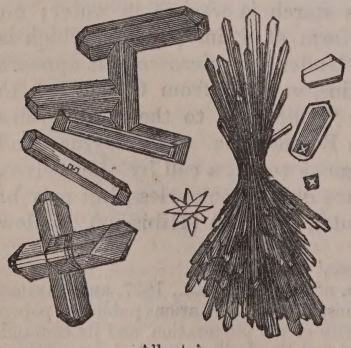
§ ἄλευρον, starch. F. aleuron., G. Klebermehl.

(Lupinus), or brown (Arachis). The grains appear to be vesicles, foveolated on the exterior; and the contents consist of the proper aleuronic matter and one or more "albines," "globides," "crystalloides," or "noyaux blancs." The albine is colourless and embedded in a vacuole or depression of the body of the grain. Many aleuron grains under the influence of water, or of iodine and water, assume a crystalline form, as rhombohedral in Sparganium; octohedra in Viola; hexahedral in Magnolia; cubic in Camarina; tetrahedral in Juniperus. All forms of aleuron grains present two characteristic reactions. A solution of iodine in water, alcohol, or glycerine stains them of a yellowish brown colour, while a solution of mercury nitrate with a drop or two of nitric acid renders them brick-red. They are soluble in water, acids, diluted alkalies and, though more slowly in glycerine, they are insoluble in alcohol, ether, and in fixed and volatile oils. Their chemical composition is not accurately known, but they contain nitrogen and are probably to be classed with the albuminous compounds. M. Hartig considers that they contain fibrin, albumin, gliadin, and casein, with which are mingled gum, sugar, and mineral salts. Like starch, from which it appears to be in some instances developed, it is of the nature of a store of reserve-nutriment. Aleuron crystals are also found in the vitellus of the ovum of vertebrated animals, forming the "yolk laminæ" of some authors. Hoppe-Seyler regards them as one of the products of the metabolic processes taking place in the protoplasmic matter of cells, but not as a true constituent of it.

Lutein.—This term has been applied by Dr. Thudichum* to a yellow substance crystallizable in rhombic plates, which can be obtained from various parts of animals and plants. It is normally present in the vitellus of the egg, in the corpora lutea of the ovary, and in the serum of blood, the cells of fat, and under pathological conditions in ovarian tumours and in serous effusions. It is also contained in the seeds, roots, leaves, and stamens of many plants. It is easily soluble in alcohol, ether, and chloroform, but is insoluble in water. Its spectrum presents three absorption bands in the blue, indigo, and violet portions of the spectrum. It crystallizes and exhibits strong attraction both for fatty and for albuminous substances. The substance termed Hæmatoidin by Holer and Städeler is Lutein; but the Hæmatoidin of Valentiner, Robin, Ruhe, and Mercier is Bilirubin or Cholophæin.

Allantoin, $C_4H_6N_4O_3$.—As its name implies, this substance is found in the allantoic fluid of the cow, but it also appears in the acid urine of fœtal and sucking animals—that is, during the period of life when the herbivora are subsisting on animal food. It has also been found in human urine after the free use of tannic acid. It crystallizes in the form of transparent rhombohedral prisms, soluble with difficulty in cold, but more easily in hot water and in boiling alcohol. It is insoluble in ether. It is closely allied to uric acid and to urea—in fact, under the influence of yeast it breaks up into urea and salts of ammonia,—and is consequently one of the terminal products of the disintegration of albumin. It is not precipitated by corrosive sublimate nor by the salts of lead. It has been found in the urine of dogs suffering from diseases of the lungs, apparently in consequence of the

Fig. 49.



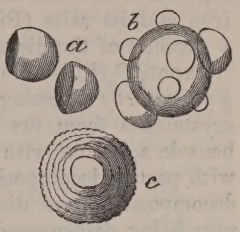
Allantoin.

* "Centralblatt," 1869, p. 1.

eficient supply of oxygen impeding the formation of the uric acid ordinarily resent.

Leucin, $C_6H_{13}NO_2$, or Amido-caproic acid, $C_6H_{11}(N_2H)O_2$, appears in the form of iridescent scales which are made up of fine microscopic needles, but often also in the form of spheroid or hemispheroidal masses, or of an aggregate of one large spheroid with several smaller ones adherent to it. The spheroids either present a concentric lamination or are destitute of this and resemble fat cells. It is destitute of taste and smell, is soluble in 27 parts of cold water, and in 625 parts of cold alcohol, sp. gr. 0·82. Its aqueous solution is neutral. It melts at 170° C. It unites both with acids and with bases. It was first discovered in putrid cheese, and is largely present in the pancreas and pancreatic juice, and is also found in the salivary glands and saliva, in the spleen, kidneys, and supra-renal bodies; in the thymus, thryoid and lymphatic glands, in the fluids of the lungs, and in pus, and occasionally in the urine, especially in cases of acute atrophy of the liver. It is either absent or only traces of it can be found in the healthy liver, brain, and muscles. It is in all probability a product of the retrogressive metamorphosis of gland tissue. It has been artificially obtained by Kühne from the action of the pancreatic ferment on albumen. Frerichs and Städeler have shown it to be probable that it undergoes decomposition in the alimentary canal, into ammonia, and the volatile fatty acids.

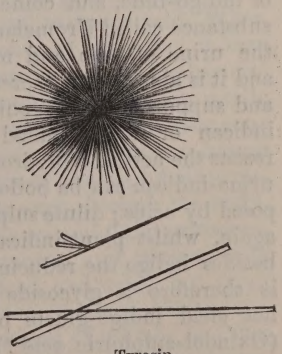
Fig. 50.



Leucin.

Tyrosin, $C_9H_{11}NO_3$.—This substance is obtained by boiling for sixteen hours one part of horn shavings with twelve times its weight of a 20 per-cent. solution of sulphuric acid, adding water. It is likewise an amido-acid and forms delicate white silky needles, which have no taste or smell, are soluble in 1900 parts of cold water and in 150 of hot, as well as in acids and alkalies. It is insoluble in alcohol and ether. When its solution is warmed with mercury nitrate the solution first assumes a beautiful red colour, and then quickly throws down a dark-brown red precipitate (Hoffmann's test). It may be obtained by boiling horn shavings or any form of albumen with strong sulphuric acid. The fluid is diluted and neutralized with milk of lime, and filtered from the gypsum. It is then evaporated, acidified with sulphuric acid, and filtered. White lead is then rubbed up with the filtrate, and a soluble tyrosin-lead is formed. The lead is precipitated with hydrogen sulphide, and the remaining fluid evaporated till the tyrosin crystallizes out. About one per cent. of tyrosin can be obtained from Ovalbumin and muscle fibrin, and about two per cent. from blood fibrin. It is contained in decaying cheese, from which it may be abstracted by water, and purified in the way above given. Tyrosin is said to be found in the spleen and pancreas, and in acute atrophy of the liver in that gland, in the brain, and in the urine; but it is probable, from Radziejewsky's researches,* that it never occurs in any organ in a normal condition, with the single exception

Fig. 51.



Tyrosin.

* Virchow's "Archiv," 1866, May.

of the contents of the small intestines, where it results from the decomposition of albuminous compounds under the influence of the pancreatic juice. Heated with concentrated sulphuric acid it forms Tyrosin-sulphuric acid together with other acids. The former gives a beautiful violet colour, with iron and its salts (Piria's test). Tyrosin, like Leucin, is to be regarded as a product of the disintegration of the albuminous compounds.

INDOL, C_8H_7N.—This substance is produced in a quantity amounting to $\frac{1}{2}$ per cent. by digesting serum-albumin or egg-albumin with pancreatic juice. It crystallizes from hot water in large shining colourless laminæ, resembling benzoic acid, but with a peculiarly nauseous smell. It melts at 52° C.; boils with partial decomposition at about 245° C.; volatilizes in a vacuum without decomposition, and distils easily with vapour of water. It is a weak base, its salts being decomposed by boiling with water. Its vapour colours a deal shaving, moistened with hydrochloric acid, deep cherry-red. Indol fused with potash is converted into anilin. Ozone passed through an aqueous solution of indol forms a small quantity of indigo-blue. It is met with in the intestinal canal as one of the products of digestion, but its precise mode of origin is unknown. Jaffe* found that on obstructing the passage of the bowels there was a remarkable increase in the amount of indigo-forming substance in the intestine, a result that was also obtained when indol was directly introduced into the intestine, the quantity of indigo being in direct proportion to the quantity of indol introduced. It would appear that indigo-forming substance is constantly present in the urine of animals fed exclusively on flesh,† and that, speaking generally, when an excess of albuminous food is consumed a similar substance appears; though when the supply of proteids is moderate and the processes of digestion and absorption are rapidly and energetically performed none is produced.

INDICAN (*Uroxanthin*), $C_{26}H_{31}NO_{17}$.—The indican, derived from Woad, the *Isatis tinctoria*, is a clear brown, intensely bitter and nauseous syrup, with neutral reaction, soluble in alcohol and ether. Its solutions are precipitated by lead acetate and ammonia. When treated with acids it breaks up into Indigo-blue and Indigo-glucin, whilst indigo-red (Heller's *Urrhodin*, Schunk's *Indigorubin*), leucin, and the fatty acids are also formed in small quantity. The same or similar changes are effected in it by ferments, especially by that associated with the putrefaction of urine. The addition of calcium chloride or a trace of chlorine gas to acid solutions of Indican causes immediate precipitation of indigo-blue, and coincidentally a substance which closely agrees with the substance called Uromelanin, $C_{36}H_{43}N_7O_{10}$. Indican is a normal constituent of the urine of man and mammals, the quantity being greatest on flesh food, and it is abnormally increased in cancer of the liver, cholera, Addison's disease, and suppurative peritonitis. Urine-indican is not identical with plant-indican or that obtained from the *Isatis tinctoria*, for whilst plant-indican resists the action of hydrochloric acid and is quickly decomposed by alkalies, urine-indican can be boiled with alkalies without change and is rapidly decomposed by acids; dilute sulphuric acid, however, having little action on it. And, again, whilst plant-indican, as just stated, on the addition of acids yields besides indigo the reducing but not fermentable substance indigo-glucin, and is therefore a glycoside; urine-indican under the same conditions does not yield indigo-glucin but sulphuric acid, and is an ether of this acid (Oxindol-sulphuric acid?).

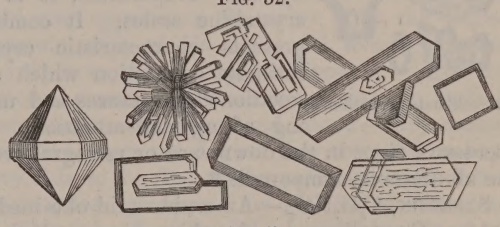
INDIGO, $C_{16}H_8N_2O_2$.—This may be obtained from the urine of the horse by evaporating to a syrup, adding an equal volume of strong hydrochloric acid,

* Virchow's "Archiv," 370, p. 1, 1877. † Hoppe-Seyler, "Physiol. Chem.," p. 333, 1878.

to which a little chlorine gas is added, so that a blue colour appears, and setting aside for twelve hours the precipitate is collected on an asbestos filter, washed with boiling water, and then with alcohol, and finally dried. It is a dark-blue powder, consisting of needles, or oblique rhombic laminæ. It is insoluble in water, alcohol, ether, alkalies, and dilute acids, but soluble in boiling chloroform, amylic alcohol, and melted paraffin. The solution in amylic alcohol exhibits a dark absorption stria between *d* and D, and the violet end of the spectrum is dark from G onwards. It sublimes at 300° C. in violet vapours. It forms two sulphacids with boiling sulphuric acid, purpursulphuric acid, and sulphindigotic acid. With boiling chromic acid the blue colour vanishes, and on cooling *Isatin*, $C_{16}H_{10}N_2O_4$, is deposited. Isatin on exposure to nascent hydrogen (zinc and hydrochloric acid) forms *Isatyd*, $C_{16}H_{12}N_2O_4$. Watery solution of isatinate of sodium treated with sodium amalgam yields on evaporation crystals of Dioxindol-sodium, from which the sodium may be removed by hydrochloric acid, yielding yellowish rhombic prisms of *Dioxindol* (hydrindin acid), $C_{16}H_{14}N_2O_4$. This exposed to nascent hydrogen is reduced to *Oxindol*, $C_{16}H_{14}N_2O_2$, a colourless substance, crystallizing in needles that are soluble in boiling water and alcohol, which when exposed to heated zinc-dust yields *Indol*, $C_{10}H_{14}N_2$, so that isatin, isatyd, dioxindol, oxindol, and indol—which last is one of the final stages of the decomposition of albuminous compounds—stand in near relation to each other.

Kreatin, or Methylglycocyamin, $C_4H_9N_3O_2$.—This substance is a constant constituent of muscular tissue, both of the striped and smooth variety, in the proportion of from 2 to 4 parts in 1000; and is found in the blood, brain, and amniotic fluid, but not in gland-tissue. It crystallizes with H_2O in oblique rhombic prisms, which are soluble in hot water, but are deposited again on cooling. It dissolves with difficulty in alcohol, and is insoluble in ether. It is prepared by exact precipitation of the phosphates in the juice of meat with acetate of lead; separation of the lead by means of sulphuretted hydrogen and careful evaporation. It is a weak base. On boiling it with baryta water it is converted into sarkosin—a substance closely related to the glycin of the bile—and urea, which immediately splits up into ammonia and carbonic acid. When heated with acids, or even after long exposure to the action of hot water, it loses two atoms of water and becomes converted into kreatinin. Under other circumstances, instead of producing sarkosin and urea, it may decompose into oxalic acid and a substance termed methyl-guanidin (uramin) which stands in close connection with guanin, xanthin, hypoxanthin, and uric acid; all of which relations are full of interest, in reference to the successive stages or planes of disintegration suffered by the albuminous compounds in their passage through the body, since nearly all of them are found in one or other of the several fluids or tissues.

Fig. 52.



Kreatin.

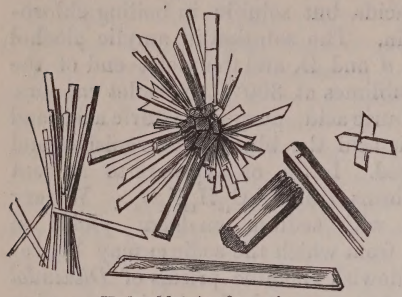
Kreatinin, $C_4H_7N_3O$, is usually associated with kreatin, and consequently occurs in muscular and nervous tissue, and in the blood and urine, but is not found in the glandular textures. Nawrocki,* however, believes his experiments prove satisfactorily that kreatinin is not a constituent of muscle, and that no conversion of kreatin into kreatinin occurs during exercise. As just shown, it may be obtained from the action of acids on kreatin. It is a powerful base,

* Fresenius, "Zeits. f. Analyt. Chemie," Band iv. 2.

and crystallizes in oblique rhombic prisms, which are soluble in water and in boiling alcohol.

GUANIN, $C_5H_5N_5O$.—An amorphous, yellowish-white substance, nearly insoluble in alcohol, ether, and water; easy soluble in acids and alkalies. By oxidation with potassium permanganate, guanin is converted into urea, oxalic acid, and oxyguanin. It constitutes the greater part of the excrements of spiders, but has also been found in the pancreas and liver, in muscle extract, and, as its name imports, in guano. It forms crystalline combinations with various acids, one of which is represented in the adjoining woodcut, and also with lime and soda.

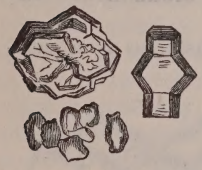
FIG. 53.



Hydrochlorate of guanin.

XANTHIN, $C_5H_4N_4O_2$.—This substance, which was first found in the form of oxide of xanthin in certain rare urinary calculi, is amorphous, and presents, both in its chemical constitution and in the places where it is found, the closest analogy to hypoxanthin. It is soluble in 1400 parts of boiling and 14,500 parts of cold water. It is soluble in ammonia, from which solution, by slow evaporation, it is again deposited in confused crystalline scales. It combines with acids, and then presents characteristic crystalline forms. The very intimate connection which exists between the three last-mentioned substances and uric acid, $C_5H_4N_4O_3$, is deserving of especial attention. They all clearly constitute successive steps in the downward or retrogressive process of metamorphosis of the albuminous compounds.*

FIG. 54.

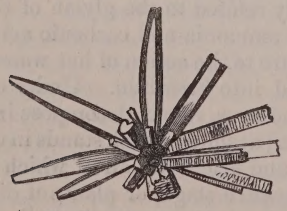


Hydrochlorate of xanthin.

SARKOSIN, $C_3H_7NO_2$.—An amido-acid obtained by boiling kreatin in baryta water. Crystallizes in rhombic prisms. It has not been certainly demonstrated to be a constituent of the body.

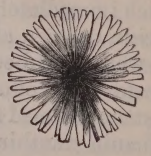
HYPOXANTHIN (*Sarkin*), $C_5H_4N_4O$, appears in the form of colourless, microscopic, crystalline granules, of no recognizable shape, which are soluble

FIG. 55.



Nitrate of hypoxanthin.

FIG. 56.



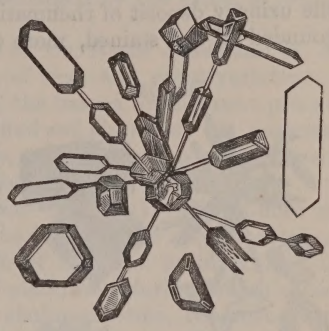
Hydrochlorate of hypoxanthin.

in 300 parts of cold and 76 of hot water, and readily dissolve in acids and alkalies. By nitric acid it is converted into xanthin. It does not appear to be a constituent of the blood in health, though it rapidly appears after death;† but it has been found in the blood and urine of leukæmic patients,‡ in muscle extract, in the liver, spleen, thymus, thyroid, kidney, and brain, and in the medulla of bones. It unites with acids to form salts, which form

* See G. Salomon, "Zeit. f. Chemie," Band ii. 1878, p. 95. † Ibid., Band ii. p. 84.
‡ Salkowski, "Archiv d. Heilkunde," Band xi. p. 1.

well-defined crystals (Figs. 55, 56). The amount of sarkin in muscle varies from 0·016 to 0·028 per cent.

Hippuric Acid, $C_9H_9NO_3$, is a glycocol in the amide group of which an atom of hydrogen is replaced by the radical benzoyl, C_6H_5CO. It is one of the constituents of human urine, though, like the last-named acid, it exists only in small quantity. It is always more abundant in the urine of the herbivorous than in that of carnivorous animals. It may be obtained from the urine of the cow or horse by simple addition of hydrochloric acid, when it crystallizes out; by re-solution and filtration through animal charcoal, it appears in the form of beautiful, transparent, colourless, four-sided prisms, which belong to the rhombic system. They are soluble with difficulty in cold water and in ether, but more easily in hot water and in alcohol. When benzoic acid is ingested, it is eliminated from the body as hippuric acid—a change that probably takes place, in part at the kidney,* but chiefly at the liver, since benzoic forms hippuric acid by taking up glycin and giving off ten equivalents of water, and it is remarkable that all the herbivora secrete bile which is rich in glycin. Hippuric acid also appears in the urine after the ingestion of bitter-almond oil, cinnamic acid, chinic acid, and toluol into the stomach. Meissner and Shephard† have shown that the hippuric acid of the herbivora is directly dependent on the nature of the aliment, since on feeding them with non-albuminous compounds—fat, sugar, and starch—they ceased to pass this acid in the urine, whilst it reappeared when they were fed on hay, straw, or clover. They believe this to be due to the presence in the latter of a body belonging to the benzole atomic group, and by a process of exclusion, that it was the thickened and infiltrated cell-walls of the epidermis cells which furnished the primary substance that by conversion yielded the acid. The most important derivatives of hippuric acid are benzoic acid and glycocol.



Hippuric acid.

Benzoic Acid, $C_7H_6O_2$.—An acid volatilizing at 240° C., crystallizing in needles or scales, soluble with difficulty in cold water, but more readily in hot water, ether, and alcohol; destitute of smell, and tastes sharp; its vapour excites a peculiar tickling in the throat; taken by the stomach in mammals it becomes converted in its passage through the system into hippuric acid, in which state it is eliminated by the kidneys, but this change does not occur in birds. It does not appear to be found in the system, but when found, as in putrefying urine, smegma præputii, and in the sweat, it results from the decomposition of hippuric acid.

Glycocol, $C_2H_5NO_2$.—A product of the disintegration of hippuric acid, obtained by boiling it with strong hydrochloric acid. It is a colourless, hard, stable body, crystallizing in oblique rhombic prisms. It tastes sweet, is insoluble in alcohol and ether, but dissolves in 4 parts of water, and melts and

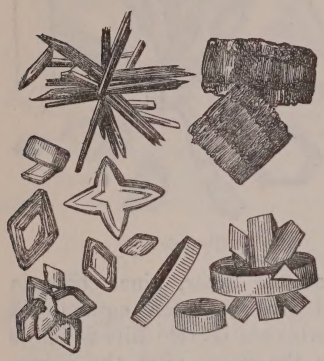
* Meissner and Shephard's "Die Hippursäure," 1866. Bunge and Schmiedeberg, "Archiv f. Exper. Pathol.," vi. 1876, p. 233. In Birds benzoic acid is eliminated, according to Jaffe ("Ber. d. Deutsch. Chem. Gesellsch.," 1877, p. 1925), in the form of a body having the formula $C_{19}H_{20}N_2O_4$, and to which he gives the name of ornithuric acid. See also A. Hofmann "Arch. f. Exper. Pathol.," vii. p. 233; and "Centralblatt," 1878, p. 310.

† "Untersuchungen über d. Entstehen der Hippursäure im thier. Organismus," 1866.

is decomposed at 170° C. It combines with metals, acids, and salts. With nitric acid, glycocol yields glycolic acid, and with ammonium permanganate it yields oxalic and other acids.

Uric Acid, $C_5H_4N_4O_3$.—When perfectly pure, uric acid appears in the form of colourless, microscopic, rhombic crystals, occasionally in six-sided plates, and sometimes in rectangular four-sided prisms; but as they are usually seen in the urinary deposit of rheumatic patients, the angles of the rhombic plates are rounded off and stained, more or less deeply, by the colouring matters of the urine. It is nearly insoluble in water, and completely so in alcohol and ether. It is dissolved by concentrated sulphuric acid, and can be precipitated unaltered on the addition of water. On subjecting it to a high temperature, it decomposes, and yields urea and cyanuric acid; with oxidizing agents, as ozone and peroxide of lead, it gives allantoin, urea, oxalic and carbonic acids. When acted on by nitric acid, and evaporated to dryness, the residue slightly moistened with ammonia assumes a beautiful purple tint from the formation of murexide. Uric acid is found in the urine, the blood, the juice of flesh, and in glandular structures, in all of which it probably exists in the condition of urate of soda. It proceeds from the decomposition of the albuminous compounds, and contains 33 per cent. of nitrogen. The proportion of N to C is as $1 : 2\frac{1}{2}$.

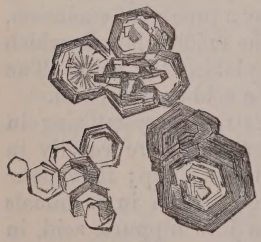
Fig. 58.



Uric acid.

Cystin (*Amido-sulphopyruvic Acid*), $C_3H_7NO_3S$; or, as Gamgee and Dewar* give it, $CH_2(H_2N)CSCO_2H$—A rare constituent of the urine of apparently healthy persons, and of renal and vesical calculi. It is normally present in the kidneys of oxen. It forms transparent, colourless, six-sided plates or tables, insoluble in water and alcohol, but soluble in mineral acids, in oxalic acid, and in caustic and carbonated alkalies. It is, however, precipitated by ammonium carbonate from its acid, and by acetic acid from its alkaline solutions. Like the foregoing substances, it is in all probability a transition stage of the decomposition of albumin or other nearly allied sulphur-holding compound.

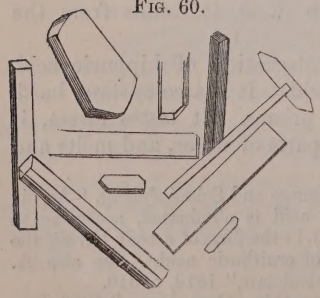
Fig. 59.



Cystin.

Urea, CH_4N_2O—*i.e.*, $(NH_2)_2CO$—crystallizes in white silky, four-sided prisms, which frequently present oblique or dihedral summits. It possesses a bitter cooling taste, like saltpetre, is deliquescent, and very soluble in water and alcohol, but somewhat less so in ether. It has no action on vegetable colours. It is decomposed at 212° F., giving off ammonia. It is not affected by potassium permanganate or ozone, but by nitric acid it is decomposed into water, nitrogen, and carbonic acid. Strong mineral acids, and the hydrates of the alkalies, as well as contact with albuminous compounds

Fig. 60.



Urea.

* "Journal of Anat. and Phys.," vol. v. p. 143.

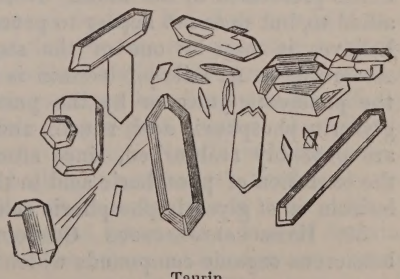
undergoing putrefaction, effect its conversion into ammonium carbonate. It unites with nitric and oxalic acids to form salts. It is isomeric with ammonium cyanate, contains 46 per cent. of nitrogen, and is one of the terminal products of the retrogressive metamorphosis of the albuminous compounds in man. Its extreme solubility, and the facility with which as a "crystalloid" it permeates animal membranes, permit it to be readily discharged by the urine, of which it is the most important organic constituent.

Animal Quinoidin.—From the experiments of Dr. Bence Jones and M. A. Dupré,* it appears there exists in the bodies of man and other vertebrata a substance which can be extracted from any of the tissues by the same process as quinine, when that alkaloid has been ingested and absorbed. It possesses nearly the same chemical properties as quinine, and its solutions give the well-known fluorescence characteristic of that alkaloid.

57. Biliary Compounds.—Cholin (*Bilineurin—Sinkalin*).—Cholin does not seem to exist in a free state in any part of the body, but it may be obtained by breaking up the lecithin contained in yolk of egg, the brain or bile, by means of boiling baryta water, the addition of platinum chloride, which causes a precipitate of a double salt of platinum and cholin chloride, treatment with hydrogen sulphide, and the decomposition of the cholin chloride with moist silver oxide. It is a thick syrup easily soluble in alcohol and water, which turns litmus-paper blue. A dilute watery solution prevents the coagulation of albumen, and dissolves both coagulated albumen and fibrin. In many points it resembles the alkaline bases. Cholin has curious relations to some well-known poisons derived from the Fungi. Thus it appears to be identical with Amanitin, the active principle of the *Amanita muscaria*, and by oxidation with nitric acid it yields Muscarin. On being heated, cholin breaks up into trimethylamin and ethyl-glycol. If the watery solution be treated with iodine water, large transparent prisms are obtained named trimethyliodo-ethyl ammonium-iodide having the formula $C_5H_{13}NI_2$, and which on heating loses the two equivalents of iodine, and is converted into Tri-methyl-vinyl-ammonium-hydroxyd, which is Liebreich's "Neurin." When heated cholin breaks up into glycol and trimethylamin, $N(CH_3)_3$. Now trimethylamin is of frequent occurrence as a result of post-mortem changes, and is probably derived immediately from the cholin, and more remotely from lecithin.

Cholalic Acid or Cholic Acid, $C_{24}H_{40}O_5$, is obtained from glycocholic acid by the action of alkalies. It crystallizes either in four-sided prisms with dihedral summits, in octahedra, or in tetrahedra, which are easily soluble in alcohol, but not readily in water or ether. On boiling with acids, or on being heated to 200° C., it yields Dyslysin ($C_{24}H_{36}O_3$), which is only soluble in ether. Cholic acid has a pure bitter taste, and when treated with nitric acid it yields acetic, valerianic, capronic, oxalic, and cholesterinic acids. One form rotates polarized light 35° to the right, the other 50°.

Fig. 61.



Taurin.

Taurin, $C_2H_7NO_3S$, is found as a constant constituent of the bile in combination with cholic acid. It has also been occasionally discovered in the blood and urine, in the tissue of the kidney, lungs, and of the striated muscles. It forms large tasteless and colourless four- or six-sided prisms, with four-sided

* "Proceedings of the Royal Society," vol. xv. No. 83, p. 73.

pyramids at their extremities. It dissolves in fifteen parts of cold water, and the solution is neutral to test-paper. Taurin is decomposed when subjected to a heat greater than 464° F.

Glycin (*Glycocol, Glycocin, or Gum Sugar*), $C_2H_3(NH_2)O_2$, is chiefly found in combination with cholic acid in the bile, but it also occurs combined with benzoic acid, as hippuric acid, in the blood and urine. It crystallizes in large colourless rhombohedral crystals, which melt at 354° F., are easily soluble in water, but with difficulty in alcohol. The solutions are acid to test-paper, and sweet to the taste. It acts both as a base to acids, and as an acid to alkalies. It originates as the product of the disintegration of gelatin and of albumin, and has been artificially formed.

Glycocholic and Taurocholic Acids, $C_{26}H_{43}NO_6$ and $C_{26}H_{45}NO_7S$.—When to a solution of crystallized ox-bile neutral acetate of lead is added, a precipitate of glycocholic acid in combination with the oxide of lead falls, and when this has been removed by filtration, the addition of the subacetate of lead to the mother liquid causes the precipitation of the taurocholate of the same metal. The amount of glycocholic acid contained in the bile of man and of the carnivora is small, but in that of the ox it is abundant. Both acids rotate the plane of polarized light to the right. Taurocholic acid is easily soluble in water, and tastes very bitter. Glycocholic acid dissolves with difficulty. Glycocholate of soda crystallizes in acicular radiating needles. Taurocholate of soda forms resinous drops. In alcoholic solution it rotates the plane of polarization towards the right 24°.5.* Pettenkofer's test for bile consists in the addition of a little cane sugar, and then of a drop of sulphuric acid to the suspected liquid, when, if either of the biliary acids be present, the fluid ssumes a bright cherry colour, which gradually deepens to purple. Nothing is accurately known respecting the origin of the biliary substances just noticed; but they are probably formed in the liver, and result from the decomposition of albuminous and oleaginous compounds.

Lecithin, $C_{44}H_{90}NPO_9$ or $C_{42}H_{84}NPO_9$, a substance regarded by Diaconow† as distearyl-glycerin-phosphate of cholin, presents the characters of a wax-like body, crystallizing with difficulty in needles from its alcoholic solution below 0° C., easily fusible, hygroscopic, soluble in alcohol, ether, chloroform, carbondisulphide, benzene, hot glacial acetic acid, and the fixed oils; on the application of heat it breaks up into cholin, stearic acid, and glycerin-phosphoric acid. Lecithin is found in all cells undergoing, or capable of undergoing development, as in the yolk of eggs, spermatozoa, white blood corpuscles, rapidly-growing tumours, the seeds and spores of plants, buds in spring, fungi, and yeast-cells; indeed, wherever vigorous metabolism is in process. It exists preformed in the brain. Nothing is known of its origin. It is closely allied to, but does not appear to proceed from, the fats. Hoppe-Seyler, indeed, believes it may be one of the steps towards the formation of the fats. According to A. Bókay,‡ lecithin is decomposed by the oleolytic ferment of the pancreatic juice or by the putrefactive ferment of the intestines into glycerin-phosphoric acid, neurin, and fatty acids. These, in the form of salts, are probably reabsorbed, since after the ingestion of lecithin with the food the excretion of phosphoric acid in the urine is augmented, whilst no trace of lecithin or of glycerin-phosphoric acid is discoverable in the fæces.

58. Hydrocarbonaceous Compounds.—The non-azotized or hydrocarbonaceous organic compounds which are used as food or which enter into the

* Dalton, "Human Physiology," 1876, p. 106.
† "Centralblatt, f. d. Med. Wiss.," 1868, Nos. 1, 7, and 28.
‡ "Zeits. fur Phys. Chemie," Band i. p. 164, 1878.

composition of the body may be divided into two groups, the saccharine and the oleaginous. The principal saccharine substances are starch, milk and grape sugar, inosit, glycogen, and the acids resulting from their fermentation. The chief oleaginous compounds are olein, stearin, palmitin, and cholesterin. Both the oily and the saccharine groups are of great importance in the processes of nutrition and development, and are scarcely ever absent either in the food, the blood, or the tissues. There can be little question that although the saccharine compounds contained in the body are chiefly derived from the farinaceous and saccharine, they partly proceed from the decomposition of the albuminous compounds, the latter change occurring especially in the liver. That a great part of the saccharine and amyloid compounds is derived directly from the food is clearly shown by the following experiment of M. Bernard.* The muscular tissue of a fasting horse was found on careful examination to be perfectly free from amyloid substances; but in the muscles of the same animal, a few hours after a full meal, clear evidence of their presence was obtained. It seems to be well established that compounds presenting a close analogy to sugar may also be obtained by the metamorphosis of oleaginous, as well as of albuminous substances within the body, of which we have examples in their continued formation in the liver, when completely absent in the food, and even during the last stages of inanition, and in their presence and gradual increase in the egg during incubation. The small quantity of sugar naturally present in the blood aids in retaining the carbonate and phosphate of lime in solution, and, according to Hoppe,† assists that metamorphosis by which fat is generated from the albuminous compounds. Most of the saccharine compounds are soluble in water and alcohol, rotate the plane of polarized light to the right, can be obtained in crystals, lose their water of crystallization at a temperature of 212°, at a little higher temperature are converted into a blackish substance termed caramel, and at a red heat are completely decomposed into carbonic oxide, carbonic acid, carburetted hydrogen, acetic acid, acetone, and other products. With oxide of lead and some other bases they play the part of an acid; on fermentation, they either yield alcohol and carbonic acid, or lactic, butyric, and formic acids.

Starch.—This is by far the most important of the hydro-carbonaceous compounds. It exists in the roots, tubers, stems, leaves, fruit, and seeds of plants, both as an amorphous and as a morphological constituent. In the former condition it is comparatively rare, but in the latter it appears in the form of separate granules, presenting, as may be well seen in potato starch, a series of laminæ arranged around an eccentrically situated point. Every starch granule consists of three kinds of substance—of *granulose*, which is coloured blue by iodine; of *erythrogranulose*, which is coloured red by it; and of *cellulose*, which is not coloured by it. If iodine be added to a starch granule, it becomes of a deep blue tint, because the granulose is by far the largest constituent; but if very little iodine be added the granule becomes of a reddish colour, because the erythrogranulose has the strongest affinity for it, and seizes upon it. On boiling with a 2 per-cent. solution of sulphuric acid, starch is rendered soluble, and is converted into Nasse's *amidulin*, which still turns blue with iodine. On longer boiling it undergoes a further change into *erythrodextrin*, or ordinary dextrin, which colours red with iodine; and after a still longer time it becomes converted into another kind of dextrin, *achroodextrin*, which tastes sweet and does not colour with iodine, and into a kind of sugar termed *glycose* (starch sugar, dextrose sugar, grape sugar). All

* "Leçons," 1859, vol. ii. p. 112.

† "Archiv f. Path. Anat." x. p. 140.

the above-mentioned bodies rotate the plane of polarization to the right. Its maximum rotating power is 103·14, the minimum 56·7.* Changes essentially similar to those just described as produced in starch by boiling with acid are effected by the action of a ferment termed diastase, which is developed in germinating seeds. Diastase breaks up starch into glycose and achroodextrin, and if fermentation continues the latter is gradually almost wholly converted into glycose.† According to MM. Musculus and Gruber‡ starch is a polysaccharide, having the formula $(C_{12}H_{20}O_{10})n$, in which n has a value of 5 or 6. When acted on by diastase and boiling dilute sulphuric acid, starch forms or breaks up successively into soluble starch; erythrodextrin; α, β, and γ, achroodextrin; maltose, and glycose. At each decomposition maltose is formed and a new dextrin of feebler molecular weight, n becoming less and less till achroodextrin γ is formed, which is probably converted into maltose by simple hydration. Maltose in its turn is disintegrated into two molecules of glycose, $C_{12}H_{22}O_{11} + H_2O$ (Maltose) $= 2(C_6H_{12}O_6)$ (Glycose). Starch constitutes an important article of diet.

Cane Sugar, $C_{12}H_{22}O_{11}$, though largely consumed as food, does not form a part of the healthy body. It forms 88 per cent. of the juice of the sugar cane, and is also obtained from beetroot. The crystals are modified monoclinic prisms, and dissolve in one-third of their weight of water, and less easily in alcohol. On boiling with water cane sugar is converted into invert sugar, or fruit sugar, which is a mixture of levulose and dextrose, and rotates to the left on account of the superior rotatory power of levulose. It appears to be converted into grape sugar partly by the action of a ferment contained in the mucin secreted by the stomach, partly by the pancreatic and intestinal juices; milk sugar as well as grape sugar probably both undergo direct absorption into the veins,§ with comparatively little change, except that a part seems to be converted into lactic acid and butyric acid.

Dextrose, or Grape Sugar, $C_6H_{12}O_6 + H_2O$, crystallizes in warty masses which are found under the microscope to consist of rhombic tablets. It is soluble in cold, and very soluble in hot water and in alcohol, but not in ether. It is capable of two kinds of fermentation—alcoholic, induced by yeast, and lactic, accompanied by the growth of a protophyte, and it is especially characterized by its power of reducing all easily reducible metallic oxides, as those of copper, bismuth, tungsten, and molybdenum in alkaline solutions. It occurs naturally in the alimentary canal as the product of the conversion of starch into sugar through the action of the salivary, pancreatic, and intestinal juices, and from thence by absorption it gains entrance into the chyle and blood. It exists in small quantities in the egg of the bird, in the amniotic and allantoic fluids of the herbivora, and occasionally in the urine of man. It is the chief or only saccharine constituent of the urine in diabetes, and it may also be made to appear in the urine by injury of the medulla oblongata.

Tests for Grape Sugar.—1. An alkaline solution reduces copper oxide to suboxide (*Trommer's Test*). 2. An alkaline solution also reduces bismuth oxide to bismuth suboxide which is black (*Böttcher's Test*). 3. Boiled with solution of potash it becomes brown, and on addition of nitric acid evolves an odour of caramel (*Moore and Heller's Test*). 4. Indigo carmine solution and sodium carbonate give with sugar solution on heating a play of colours—green, purple, red, yellow (*Mulder and Neubauer's Test*). 5. Sugar evaporated to dryness with H_2SO_3, or HCl, leaves a black shiny residue (*Runge and Reich's Test*). 6. Grape sugar boiled with silver nitrate and ammonia deposits metallic silver.

* Béchamp, "Rev. Scient." 1877-1878, p. 427. † See Brücke, Vorlesungen, 1874, p. 221.

§ "Compt. Rend. de l'Acad. des Science," June 10, 1878.

7. Alcoholic solution of grape sugar mixed with alcoholic solution of caustic potash gives a white flocculent precipitate of grape sugar and potassium. 8. The Fermentation Test. 9. On boiling with a mixture of cupric sulphate and potassium sodium tartrate dissolved in caustic soda (Fehling's solution) the copper is reduced.

Lactose, or Milk Sugar, $C_{12}H_{22}O_{11} + H_2O$, exists in the proportion of from 3 to 5 or 6 per cent. in the milk of various animals. It is feebly saccharine to the taste, and is gritty to the teeth, and is less soluble than dextrose. Like grape sugar it reduces the salts of copper in an alkaline solution, and rotates the plane of polarization to the right. Lactose undergoes lactic, but not readily alcoholic fermentation.

Glycogen, $C_6H_{10}O_5$ (*Liver Sugar*).—This remarkable substance was first obtained by C. Bernard by immersing the livers of various animals, within a few seconds of their death, in boiling water, to coagulate the albumen, then bruising the mass in a mortar and filtering the liquid through animal charcoal. On the addition of alcohol in excess or of glacial acetic acid, the glycogen is precipitated as a white and tasteless amorphous material soluble in water, and then forming an opalescent solution, but incapable of effecting the reduction of the salts of copper. Brücke* has lately recommended the double iodide of mercury and potassium as the best means of completely precipitating pure glycogen. The solution is prepared by precipitating solution of corrosive sublimate with potassium iodide, washing the precipitate and dissolving it in hot solution of potassium iodide till the latter is saturated with it. Pure glycogen may now be obtained by first placing the liver in boiling water, then bruising it in a mortar, returning it to the same water, and boiling it for ten minutes; filtering and rapidly cooling the solution with ice or a refrigerator. Hydrochloric acid and the mercurial solution are then alternately added as long as any precipitate falls, the fluid is filtered and alcohol added to the filtrate till an abundant precipitate of glycogen takes place. This is washed successively with weak alcohol, strong alcohol, and absolute alcohol, and finally purified with ether. Glycogen thus obtained is free from nitrogen and leaves no ash when burnt. It is coloured red with iodine, not brown. Under the action of dilute acids, with the exception of nitric acid, glycogen is converted into dextrose, and the same effect is produced with all amylolytic ferments, as ptyalin and amylopsin. It rotates the plane of polarization to the right. Glycogen has been found to be constantly present in the muscles, in all embryonic tissues, in the placenta, testes, brain, and white blood corpuscles; in the notochord, and in cartilage, whether hyaline, fibrous, or elastic,† but only very small traces of a substance, the identity of which with glycogen was somewhat doubtful, can be obtained from the blood, spleen, kidneys, or secreting mammary gland, so that it can scarcely be admitted that it is stored up in the body as a preliminary stage of the formation of milk sugar. All muscles yield sugar, part of which appears to present identity of composition with grape and liver sugar, whilst part possesses distinctive characters, and has received the name of Inosit. Weiss‡ found that muscular activity was associated with a marked decrease in the per-centage of glycogen in the case of frogs, amounting to a quarter of the total normal quantity. The heart, however, in spite of its constant activity, contains (in the dog) two-thirds as much glycogen as ordinary muscular flesh.

Inosit (*Muscle Sugar*), $C_6H_{12}O_6 + 2H_2O$, is a kind of sugar which was originally found in the expressed muscle juice of the heart;§ but exists also in the pancreas and thymus glands; in the lungs, kidneys, liver, and spleen;‖ in the brain¶ and

* "Wien Akad. Ber." Band lxiii. Feb. 1873. † Neumann, "Archiv f. Mik. Anat." Heft 1.

¶ Müller, ibid., Band ciii. p. 140.

suprarenal capsules of the ox. In disease, as in diabetes and Bright's disease, it occurs in the urine. It is identical with the Phaseomannite found in beans, and it is found elsewhere in the vegetable kingdom. It crystallizes in long rhomobhedra, which are at first transparent, but subsequently become opaque. It possesses a feebly saccharine taste, and has no power of rotating the plane of polarized light; nor does it, like some other kinds of sugar, reduce the salts of bismuth, copper, or silver in an alkaline solution. A good test for it, suggested by Scherer, consists in heating to dryness the supposed mass with a little nitric acid in a porcelain dish, then moistening it with chloride of calcium, and again evaporating it, when a rose-red mass remains. It does not undergo alcoholic fermentation, but when in contact with decomposing albuminous bodies it yields lactic and butyric acids; or, according to Helger,* sarcolactic acid. The experiment of tetanizing an animal for a considerable period of time, performed by P. Spiro,† shows that after prolonged muscular exertion sarcolactic acid, probably derived from the decomposition of inosite, is contained in considerable quantities in the blood.

Chondroglycose.—This form of sugar is obtained from chondrin when it is exposed to concentrated and boiling hydrochloric acid, or to the influence of gastric digestion. It crystallizes with difficulty, rotates the plane of polarized light to the left ($-46°{\cdot}5$), and is only partially capable of undergoing fermentation, a part refusing to ferment; and the solution after fermentation only rotating polarized light to half the extent. Chrondroglycose forms an easily soluble combination with lime.

Formic Acid, CH_2O_2.—This is a colourless fluid with peculiar odour, crystallizing below 0° C. The vapour is combustible, and highly irritating (raising a blister when applied to the skin). Heated with concentrated sulphuric acid it yields carbonic oxide and water. Iron chloride gives a blood-red colour with solutions of its salts. The acid is free or combined with bases in ants, in the stings and poisonous secretions of various insects, and in the stinging hairs of the procession caterpillar; in the sweat; in the juice of the spleen, pancreas, and thymus; in muscle juice; in the brain; in the blood in leukæmia, and in the urine. Formic acid is generally a product of the disintegration of organic bodies, as of the albuminoids, whilst it also results from the action of ozone on glycerine, the fats, and fatty acids. It is probably one of the final products of the disintegration of the albuminous compounds in the animal body.

Acetic Acid, $C_2H_4O_2$.—A colourless, pleasant-smelling, inflammable fluid, having when concentrated a sp. gr. of 1·063, crystallizing at 5° C., boiling at 119° C. When distilled with strong bases it furnishes acetone. Nitrate of silver added to solutions of neutral acetates gives a white crystalline precipitate soluble in ammonia. Like formic acid, it is one of the final products of the metabolism of the albuminoid compounds. It has been found in the sweat, in the juice of muscles, of the spleen and other glands, and in the blood of leukæmic patients; also in the blood of animals the food of which has been saturated with brandy, and sometimes in the stomach after the use of much saccharine or amylaceous food.

Lactic Acid, $C_3H_6O_3$.—Of this acid there are two isomeric modifications—fermentation, or ethidene lactic acid, and β-lactic or ethene lactic acid, which last is of little interest to the physiologist.

Ethidene lactic acid, called *isolactic* and *fermentation lactic acid*, is the ordinary lactic acid produced by a peculiar fermentation of sugar and other carbohydrates, which occurs at temperatures between 20° and 40° C. (58°—104° F.), and requires the presence of water and certain ferments—viz., albuminous substances in a peculiar state of decomposition, such as casein, glutin, or animal

* Müller, ibid., Band clx. p. 333. † "Zeits. f. Physiol. Chemie," 1878, Band i. p. 111

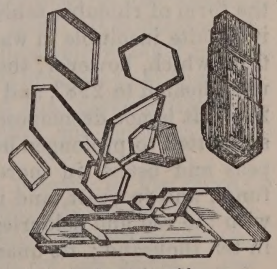
membranes, especially the mucous membrane of the stomach of the calf (rennet) or of the dog, or bladder. According to Pasteur, it depends on the presence of a peculiar fungus—the *Penicillium glaucum*. In its most concentrated condition it is a strongly acid, tasteless and odourless syrupy fluid, which under certain conditions gelatinizes. Its sp. gr. is 1·215. It is readily soluble in all proportions in water, ether, and alcohol. It is not volatile, and expels volatile and some mineral acids from their combinations at high temperatures. It breaks up into carbonic acid and carbonic oxide gases, aldehyde, and other compounds. When placed in contact with decomposing animal substances it decomposes into butyric acid, carbonic acid gas, and hydrogen.

Sarcolactic acid, or *paralactic acid*, is a form of lactic acid existing in the animal organism, especially in muscle, from which it may be extracted by cold water or dilute alcohol. It is most easily prepared from Liebig's extract of meat. It agrees in all its reactions with fermentation lactic acid, and must therefore be an ethidene-lactic acid, but differs from it in rotating the plane of polarization to the left, whereas ordinary lactic acid is optically inactive. Lactic acid, either free or in combination, is widely distributed in the body. Fermentation lactic acid, for example, has been found in the gastric juice, in the contents of the small and large intestine, and in the chyle of the thoracic duct of horses after abundant amyloid food; whilst sarcolactic acid exists in the juice of both striated and unstriated muscle in ox-gall, and in the fluid of ovarian cysts. Lactic acid, though of which form has not been determined, is found in the juice of the spleen, liver, thymus, thyroid, pancreas, lungs, and brain; as a sodium salt in the allantoic fluid of the cow, and as a calcium salt in the urine of the horse. It is also found in many pathological conditions, as in the milk if too long retained, in the blood in leukæmia, pyæmia, and puerperal fever, in purulent extravasations, in the urine of patients suffering from rachitis and osteomalacia, and trichinosis, and especially from acute atrophy of the liver in poisoning by phosphorus; in the latter two cases probably in the form of sarcolactic acid. It has also been noticed in the saliva in diabetes, and in the sweat in puerperal fever. The lactic acid found in the body proceeds then from two sources—from fermentative changes in the food, and from regressive metamorphosis taking place in the tissues, and in the case of muscle, of the sugar it contains.

Glycerin-phosphoric Acid, $C_3H_5(OH_2).O.PO(OH)_2$.—This acid may be prepared by gradually adding powdered metaphosphoric acid to cooled glycerin. Combination takes place with considerable elevation of temperature. It may also be obtained from the yolk of egg. It forms a sour syrupy liquid, which breaks up at a moderately high temperature into glycerin and phosphoric acid.

Succinic Acid, $C_4H_6O_4$.—A very stable organic acid, crystallizing in rhombic prisms and rhombohedric plates; it is tasteless, and dissolves easily in water. It occurs in the parenchymatous juices of the spleen, thymus, and thyroid glands of the ox, in the urine of the herbivora, in the contents of cysts containing echinococci in man, in the fluid of hydrocele, in cases of hydrocephalus, and in considerable quantity in the blood of the rabbit, goat, ox, and horse. It appears to belong to a series of acids obtained by the action of powerful oxydizing agents on fats, and is one of the terminal products of their disintegration. It can be obtained from the oxidation of butyric acid, malic acid, and asparagin, to the use of which last substance its occurrence in the urine is probably usually due.

Fig. 62.



Succinic acid.

Oxalic Acid, $C_2O_2(OH_2)$, is frequently found in urine after the use of certain kinds of vegetable food. In combination with lime it constitutes a formidable variety of calculus. It is a constantly-occurring product of the oxidation of organic bodies, and stands in close relation with uric acid.

59. Oleaginous Compounds.—The animal fats are glycerides, *i.e.*, compound ethers of the trivalent alcohol glycerin and the fatty acids. Those usually present are tripalmitin, tristearin, and triolein, which are represented by the formula:—

Tristearin (Tristearic Acid Glyceride) $\left.\begin{matrix}(C_{18}H_{35}O)_3\\C_3H_5\end{matrix}\right\}O_3$

Tripalmitin (Tripalmitinic Acid Glyceride) $\left.\begin{matrix}(C_{16}H_{31}O)_3\\C_3H_5\end{matrix}\right\}O_3$

Triolein (Triolinic Acid Glyceride) $\left.\begin{matrix}(C_{18}H_{33}O)_3\\C_3H_5\end{matrix}\right\}O_3$

These are associated in human fat in the proportion of about three-fourths of stearin and palmitin and one-fourth of olein. The mean per-centage composition of human fat is C 76·62, H 11·94, O 11·44, expressed by the empirical formula $C_{62}H_{99}O_6$. The substance formerly called margarin is a mixture of tripalmitin and tristearin. A separation of these proximate principles within the cells may occasionally be observed at low temperatures; the more solid fats, tripalmitin and tristearin, appearing as a minute stella of crystalline form, surrounded by the still fluid triolein. Exposed to the action of superheated steam they break up into the fatty acids and glycerin. All the animal fats are soluble in hot alcohol, in ether, fluid oils, benzole, carbon disulphide, and in chloroform. They are distinguished from one another by the temperature at which they respectively solidify, and by the salts that they form with the alkalies.

The following Table shows about the proportion in which they are found in some of the fluids and tissues of the body:—

	Per-centage of fat.		Per-centage of fat.		Per-centage of fat.
Sweat	0·001	Blood	0·4	Milk	4·3
Vitreous Humour	0·002	Cartilage	1·3	Cortex of Brain	5·5
Saliva	0·02	Bone	1·4	Brain (whole)	8·0
Lymph	0·05	Bile	1·4	Hen's Egg	11·6
Synovia	0·06	Crystalline Lens	2·	Medulla of brain	20·
Liq. Amnii	0·06	Liver	2·4	Nerves	22·1
Chyle	0·2	Muscles	3·3	Spinal Cord	23·6
Mucus	0·3	Hair	4·2	Adipose Tissue	82·7

Cholesterin, $\left.\begin{matrix}C_{26}H_{43}\\H\end{matrix}\right\}O + H_2O$ (or *biliary fat*), is a hard, spermaceti-like substance, constituting the greater part of gall-stones, and separating from its solutions in nacreous scales that are found under the microscope to have the form of rhombic tablets, the obtuse angle being 100° 30′, the acute 79° 30′: it is quite insoluble in water, but is soluble in ether, and also in boiling alcohol, from which, however, the greater part separates on cooling. It does not melt until heated to 298°, and it solidifies again and becomes perfectly crystalline at 275°. It is not decomposed by concentrated alkalies even when the mixture is submitted to prolonged heat. It is widely distributed in plants,* being found in peas and beans, in increasing amount as they ripen, in young rosebuds, in fungi, and in yeast, and is constantly present in the blood (chiefly in association with the red and colourless corpuscles) in the proportion of about two parts in ten thousand; its quantity seems to be augmented in old age. It is found

* Beneke, "Annalen Chem. Pharm." Band cxxii. p. 249, and cxxvii. p. 105. Ritthausen, "Chem. Centralblatt," 1863, p. 500. Hoppe-Seyler, "Physiologische Chemie," 1877, p. 81. Lindenmeyer, "Beiträge zur Kenntniss des Cholesterins, Inaug. Dissert." 1863.

also in the bile, in lymph and meconium, the spleen, and in most glands, in the yolk of egg and in spermatozoa, and is stated to be a constituent of the nervous tissue, being probably a product of the disintegration of the nerve substance. It is frequently separated from the blood as a morbid product; thus it is often present in considerable quantity in dropsical fluids, and particularly in the contents of cysts. It is occasionally seen in disorganized eyes, floating in detached scales in the fluid vitreous, and is sometimes deposited in the solid form in degenerated structures, tubercular concretions, &c. It is not present in the fæces, except after long fasting, being normally converted into stercorin as it passes down the intestine. Strong arguments have been adduced by Dr. Austin Flint* for regarding it as an excrementitious principle discharged by the liver, and hardly second in importance to urea. He has found it always more abundant in the blood returning from the brain than elsewhere; also that its quantity is exceedingly small in the venous blood of the paralysed side in hemiplegia; and that in cases of serious structural disease of the liver, accompanied by symptoms pointing to blood-poisoning, cholesterin accumulates in the blood, constituting a condition which he has called Cholesteræmia.

Valerianic Acid, $C_5H_{10}O_2$.—A colourless oily fluid, of penetrating cheesy odour and pungent taste. It forms an oily spot on paper, which disappears on being heated; when concentrated it is inflammable. It is readily soluble in alcohol and ether, but requires 30 volumes of water for solution. It boils at 175° C., but remains fluid at −15° C. Neither this acid nor capronic acid, $C_6H_{12}O_2$, caprylic acid, $C_8H_{16}O_2$, nor capronic acid, $C_{10}H_{20}O_2$, have been shown to be certainly present under physiological conditions in the body, though it is not improbable that one or more of them may be found in the sweat and in the blood.

Propionic Acid, $C_2H_6O_2$, when concentrated is an oily colourless fluid, crystallizing in laminæ at a low temperature, and boiling at about 140° C. It has a peculiar smell and a burning taste. It is doubtful whether it forms a constituent of the animal organism, though it may probably exist in the juices of some glands and in the blood in leukæmia. Its artificial production by oxidation of the albuminous compounds and of the fatty acids, is in favour of this view. Von Gorup Besanez† states that he has obtained it as a product of the oxidation of glycerin by ozone in an alkaline solution. Schottin believes it to be present in the sweat, and C. Schmidt in the gastric juice.

Butyric Acid, $C_4H_8O_2$.—An oily colourless fluid, smelling strongly of rancid butter, with pungent taste; sp. gr. 0·97; boils at 157° C.; remains solid even at −20° C.; burns with a blue flame. Its combinations with alkalies are volatile and non-crystallizable. It has been found in the sweat, in the juice of muscles, of the spleen and other glands, occasionally in the urine, in the contents of the stomach, and in vomited matter, in the contents of the cæcum, and in the solid excrement after the use of vegetable food. It is discharged by some beetles of the genus Carabus. It has not been certainly found in the blood. Its occurrence in the alimentary canal is attributable to changes in the constituents of the food, especially as it is known that carbohydrates in presence of organised ferments constantly undergo butyric and lactic acid fermentation.

Phenol.—Traces of this substance are constantly present in the fæces.‡ Like Indol, it appears as one of the products of the changes occurring when albuminous substances and the pancreas are undergoing putrefactive decomposition.§ The incarceration of a portion of intestine, or the arrest of the

* "Physiology of Man," vol. ii. p. 402. † "Physiolog. Chemie." 1874, p. 296.

§ Baumann, "Zeits. f. Physiol. Chemie," Band i. p. 60, 1877.

onward movement and absorption of the contents of the intestine, if these are rich in proteids, leads to the appearance of phenyl-sulphuric acid in the urine.* The mode in which it arises, however, whether as a simple product of decomposition of albumen with absorption of water, or as a reduction process, is unknown.

Skatol, C_9H_9N.—This, like Indol, is one of the products of the disintegration of albumen. It is obtained in the form of shining laminæ, melting at 95° C., by washing fæces with a solution of acetic acid and distilling. The distillate is neutralized with sodium carbonate, and shaken with ether. After evaporation of the ether, the residue is boiled with hot water, from which on cooling skatol is deposited.† It is to this substance that the odour of the fæces appears to be chiefly due.

Stercorin.—This term has been applied by Dr. Austin Flint to a peculiar substance, crystallizing in needles, which may be extracted from normal fæces by the successive action of ether, alcohol, and a hot solution of caustic potash, by which all the saponifiable fats are removed. On largely diluting the mixture with water, filtering, acting on the residue with ether and alcohol, and evaporating, pure stercorin may be obtained. It resembles cholesterin in many points, and is believed to proceed from that substance. Its crystalline form is, however, different, and it fuses at a lower temperature—96°·8 Fahr. About ten grains are eliminated per diem.

60. Inorganic Compounds.—The principal inorganic compounds that form part of the tissues and fluids of the body are water carbonic acid, and ammonia; the carbonates, chlorides, sulphates, and phosphates of the alkalies and alkaline earths, and potassium sulpho-cyanide. *Water* is the most widely distributed of all the constituents of the body, and forms rather more than half its weight (59 per cent.), the different tissues, however, containing very various amounts, from the enamel of the teeth, which has only 2 per 1000, to the renal tissue, which has 827 per 1000. Fat contains 209 per 1000; the tissues of the liver, 693; of the spinal cord, 697; of the skin, 720; of the brain, 750; of the muscles, 757; of the spleen, 758; of the thymus, 770; of the nerves, 780; and the heart, 792 parts in 1000. It is for the most part directly ingested, but a small portion is probably also formed in the body, as one of the terminal products of the various chemical changes undergone by the more complex substances used as food. It is discharged from the body by the kidneys, skin, lungs and bowels. It confers elasticity, extensibility, and translucency on the several tissues. It is a general solvent, and is essential for all processes of imbibition, diffusion, and of movement in general, both in a chemical and physical sense. By its evaporation, a large amount of heat is rendered latent, and it hence serves as the chief heat regulator of the body. The physiological significance of the various *saline constituents*, except in so far as they form part of the bony skeleton, has not been satisfactorily ascertained, though in some instances it is probable they serve to retain in solution some of the organic compounds. With the exception of common salt, they are rarely taken into the body in their chemically pure state, being usually combined with the organic constituents of the food, and are not less important than these in the general processes of nutrition. In some few instances they appear to be formed in the body, as in the case of the alkaline sulphates and phosphates, the former of which, whilst partially consumed with the food, are in part derived from the oxidation of the sulphur contained in the albuminous compounds, whilst the latter in part proceed from the oxidation

* Salkowski, "Ber. d. Deutsch. Chem. Gesellschaft," Band ix. p. 1595, 1876.
† Nencki, "Centralblatt für die Med. Wiss,' 1878, p. 849.

of phosphorus in organic compounds. The salts ingested are eliminated for the most part unaltered by the kidneys and bowels. The chief exceptions to this rule are found in the salts of the vegetable acids as the tartrates, malates, and citrates, which undergo decomposition in the blood, and are discharged in the condition of carbonates. The most widely-distributed, as well as perhaps the most important salt in the body is *sodium-chloride*, or *common salt*. The blood contains rather more than 4 parts of it in 1000, and the proportion undergoes but little variation, whether an excess or a deficiency be ingested with the food—in the one case the superfluous quantity being quickly eliminated by the urine, and in the other, the system retaining its hold of the salt with such pertinacity that the quantity discharged falls to a minimum, or its elimination is altogether arrested. Dr. Broadbent* has pointed out that this retention can only be in virtue of a special chemical relation between the salt and the animal tissues and fluids, and it is in consequence of such affinity that it, as well as other salts, are of service in the organic processes. It is present in considerable quantity in chyle, lymph, and white of eggs; in the salivary and gastric fluids; in mucus, pus, and inflammatory exudates; whilst it is remarkably deficient in the yolk of eggs, in the juice of muscles, and in the secretion of some glands. Its uses are numerous. It exerts an important influence on all the diffusion processes that take place in the body, affecting in this way the absorption and interchange of material; whilst by conferring, in association with other salts, a certain density upon the blood plasma, it plays an important part in the conservation of the morphological elements of the blood in their natural condition. It also seems to be essential to the performance of many of the metamorphic and histogenetic operations to which the organic constituents of the food are subjected in the animal economy. It was demonstrated by Boussingault,† that when, of two sets of oxen, one was allowed the unrestricted use of salt, whilst the other was as far as possible deprived of its use, a marked contrast was observable in the course of a few weeks between them, and manifestly to the advantage of the former. The desire for common salt on the part of animals and man is extremely powerful, leading the former, especially if they be vegetable feeders, to traverse great distances to reach saline deposits: whilst strong evidence of the necessity for its use in man is afforded by the fact mentioned by Brücke, that many military deserters who live a wild life in the mountains of Salzburg, Upper Australia, and Carinthia, risk their liberty and even lives to obtain it in town or village. Its importance is also shown by the circumstance,‡ that if salt be completely excluded from the food for three days, albumen appears in the urine. *Disodium orthophosphate* (Na_2HPO_4) and sodium *carbonate*, the latter of which is partly ingested with the food, and partly results from the decomposition of the salts of malic, citric, and tartaric acids, would seem to have as their chief purpose the maintenance of the alkalinity of the blood, on which depends not merely the solubility of its albumen, but the facility of its passage through the capillaries, and the readiness with which its combustive materials are oxidized, whilst they also increase the absorptive power of the liquor sanguinis for gases, and thus play an important part in the respiratory process. The salts of *potash* appear to be specially required for the nutrition of the muscles and nerves, since they are largely present in the fluids and ashes of those tissues, but they probably exert the same general influence as those of soda. The quantity present in the

* "An Attempt to apply Chemical Principles in Explanation of the Action of Remedies and Poisons." 1869.

† "Mémoire de Chemie Agricole," 1854, p. 271.

‡ Jaccoud, "Nouv. Dict. d. Sci. Med." vol. i. p. 536.

blood cannot exceed certain limits, since the observations of Grandeau and others* have shown that the injection of potassium salts, and especially of potassium chloride, are even in dilute solution highly poisonous, paralysing the heart and striated muscles. It is remarkable that when injected into the stomach the action of potassium chloride is different, increasing the frequency and force of the heart's action, and the pressure of the blood.† The presence of the earthy salts, on the other hand, would seem to have reference almost exclusively to the composition of the tissues, into which some of them enter very largely. *Calcium phosphate*, in particular, must be regarded almost in the light of a histogenetic substance so constantly is it present in newly-forming tissues, whilst it is also in great demand as the principal consolidating material of bone and tooth. Whether the *calcium carbonate*, *magnesium phosphate*, the *calcium fluoride*, and the *silica* of the blood, are of any other use than to supply consolidating materials for the tissues, there is at present no evidence whatever. *Iron*, like the alkaline salts, is an essential constituent of the blood itself, forming a large per-centage of the hæmoglobin of its red corpuscles, and it is supplied by the blood to various tissues, especially the muscles and the hair, of which also it may be considered an essential component. Estimating the quantity of blood with Bischoff (highly) at 7·7 per cent. of the whole weight of the body, the total quantity of iron contained in the blood of a man, weighing about 150 lbs., would be 45 grains. The normal proportions of all these substances are essentially maintained by means of the excretory apparatus, which filters off (so to speak) any surplus, it being through the urinary organs that they are chiefly eliminated. And it is by them, too, that the normal proportion of water in the blood is maintained; the Malpighian apparatus of the kidneys apparently acting as a kind of safety valve, through which any surplus that remains after the cutaneous, pulmonary, and intestinal exhalants have performed their appropriate duties, is allowed to make its escape.

CHAPTER V.

OF FOOD, AND THE DIGESTIVE PROCESS.

1. *Of Food, its Nature and Destination.*

61. From the foregoing observations regarding the composition of the tissues and fluids of the body, it may be concluded that the substances which are required by animals for the development and maintenance of their fabric are of two kinds, the Organic and the Inorganic. The Organic alone are commonly reckoned as aliments: but the latter are really not less requisite for the sustenance of the body, which speedily disintegrates if the attempt be made to support it upon any Organic compounds in a state of purity. In all ordinary articles of diet, however, the Inorganic matters are present in the requisite proportion; and hence it is that the necessity which exists for their employment has very commonly escaped notice.

62. The Organic compounds usually employed as food by Man are partly derived from the Animal, and partly from the Vegetable Kingdom; and they may be conveniently arranged under the three heads already mentioned of the Saccharine, the Oleaginous, and the Albuminous—under which last

* Traube, Bernard, Ranke, Podcapäw, and Guttmann.
† Kemmerich, "Archiv f. Phys." Band ii. p. 49.

gelatine is included. There are many other substances, however, which, though truly alimentary and consumed to a considerable amount, cannot be legitimately placed under either of the above heads—such are, for example, the vegetable acids, and pectine, or vegetable jelly. The compounds belonging to the *Saccharine* group consumed as food, though existing in small proportions in the animal tissues and fluids, are principally derived from the vegetable kingdom, in which they are frequently present to a large amount. It is probable that cane-sugar undergoes conversion into a special form of sugar either at the liver or soon after it has entered the blood. Starch is for the most part converted into amidulin, erythrodextrin, achroodextrin, dextrin, and a peculiar form of sugar; and by a further process of oxidation or combustion after absorption these compounds generate carbonic acid, which is chiefly eliminated by the lungs, and thus become directly subservient to the generation of nervo-muscular force, and to the maintenance of the heat of the body. That the saccharine substances are *per se* insufficient for the maintenance of life has been shown by numerous experiments upon animals, and by the interesting experiments of Dr. Hammond,* who on one occasion limited himself to a diet of 1½ lb. of gum per diem, and on another to a similar quantity of starch and water. In both sets of experiments hunger, debility, and febrile excitement were soon experienced, and he was finally compelled to discontinue the gum diet on the fourth day, though he was able to persevere in the use of the starch till the tenth—a circumstance which was probably partly due to its still retaining a small proportion of gluten, and partly to its not producing such serious disorder of the stomach and bowels as the gum.

63. The *Oleaginous* compounds (§ 59) which enter so largely into the composition of the body,—being not only stored up in masses in the adipose substance, but also forming constant and important constituents of the muscular, nervous, and other tissues,—are partly introduced into the system from without, and are also partly the result of the chemical metamorphoses effected within the body upon the albuminous and saccharine compounds: by which means the latter become subservient to the nutrition of the several nitrogenous as well as non-nitrogenous tissues. In the diet of the Carnivora, the fats almost entirely replace the carbohydrates consumed by the Herbivora. Previous to absorption the oleaginous substances undergo fine division, and, perhaps, to some extent saponification; whilst after their entrance into the circulation they are partly applied to the purposes of nutrition, partly to the production of nervo-muscular force, and partly, there is good reason for believing, combine immediately with oxygen, and thus support the animal heat. Like the saccharine, the oleaginous compounds when consumed alone are wholly incapable of supporting life; and the only benefit that a starving animal obtains from their consumption is the maintenance of its temperature, and a consequent slight prolongation of its life; death occurring, as has been shown by Mr. Savory, when non-nitrogenous food is freely supplied,† not from loss of temperature, as in inanition, but from loss of tissue. The experiments of Dr. Ed. Smith on the elimination of carbonic acid, and of MM. Fick and Wislicenus, and Dr. Parkes, on the excretion of nitrogen during rest and exercise, as well as the more theoretical considerations adduced by Professor Frankland, alike tend to show that during the period of active exertion the nitrogen-holding substance of the muscles undergoes comparatively trifling increase in the disintegration to which it is constantly sub-

* "Experimental Researches on Food," Philadelphia, 1857.

† "Proceedings of Royal Society," May 1, 1862.

ject, whilst a marked increase occurs in the oxidation of the hydrocarbonaceous constituents; the union of these with oxygen, or their combustion, appearing to generate the force which is rendered apparent in locomotion or manual labour. Hence it is found that considerable, and with healthy muscles even prolonged, exertion can be made on food containing little or no nitrogen —as, for instance, on biscuits made of starch and sugar, or starch and fat. General experience, however, as well as the experiments of Dr. Hammond and Mr. Savory—as we have already seen—and especially those of Dr. Parkes, which will hereafter be more fully discussed, show conclusively that there is a limit to the muscular force which can be exerted under such circumstances; and that when food has been administered which is either altogether deficient in nitrogen, or which contains an insufficient supply of that substance, sooner or later the power of the muscles diminishes, and at length altogether fails. It may therefore be regarded as a well-established fact that when severe and sustained muscular exertion is required to be performed, the food must contain not only a due supply of hydrocarbonaceous and easily oxidizable substance which may develop the muscular force, but also a sufficient amount of nitrogenous material to repair the waste of tissue which occurs in the act of contraction.

64. The substances forming the *Albuminous* group (§ 56) are applicable to the support of the Animal body, both by affording the materials for the nutrition and re-formation of its tissues, and also by serving for the maintenance of its heat, and the production of muscular force, through the decomposition of which they are susceptible, into hydrocarbonaceous matters capable of undergoing direct oxidation, and highly-azotized compounds which ultimately pass-off by the kidneys. The proportions of carbon, hydrogen, oxygen, and nitrogen, of which all these substances are composed, appear to be very similar; and they seem all capable of being reduced by the digestive process to a like condition. Hence it is a matter of little consequence, except as regards their digestibility and the proportion of inorganic matters with which they may be respectively united, whether we draw our histogenetic materials from the flesh of animals (myosin, syntonin), from the white of egg (albumen), from the curd of milk (casein), from the grain of wheat (gluten), or from the seed of the pea or bean (legumin). Neither of these substances, however, can long sustain life when it is used by itself; for it has been experimentally ascertained, that by being made to feed constantly on the same substance (boiled white-of-egg, for instance, or meat deprived of the osmazome that gives it flavour), an animal may be effectually starved; its disgust at such food being such, that even if this be swallowed, it is not digested. Thus Dr. Hammond limited himself for a period of ten days to a diet of about 1½ lb. of albumen obtained from the serum of bullock's blood, and 4 lbs. of distilled water per diem. Little inconvenience was experienced until the fourth day, when loss of appetite, headache, and debility were felt. The severity of these symptoms rapidly increased, and the disgust which the monotony of the diet occasioned was so great, that it was with much difficulty the albumen could be eaten. On the seventh day, albumen appeared in the urine; and on the ninth, such severe diarrhœa set in that he was compelled to give up the experiment. There was no failure in the maintenance of the temperature of the body, though its weight was notably diminished at the end of the experiment, and the mental faculties remained clear throughout.—The value of *gelatin* as a food, nearly allied as it is to the albuminous compounds, seems to be small, and it certainly cannot permanently replace albumen as an article of diet. The nutritive value of soups and broths are probably chiefly attributable to the albuminous

matters which they hold in solution, though it may also in some measure be due to the readiness with which their gelatinous constituents can be absorbed and applied to the purposes of nutrition and calorification. The very large quantity of gelatin which Bischoff and Voit found it necessary to make their dog consume in order to maintain its weight,—a quantity of *dry* gelatin, in fact, equal to the weight of moist flesh on which the animal was ordinarily fed,—is worthy of particular notice, and indicates either that little is absorbed, or that when absorbed it is not readily applied to the nutrition of the tissues. When consumed in large quantities it increases the specific gravity of the urine and the amount of urea it contains.* It is very interesting to remark (with Dr. Prout) that, in the only instance in which Nature has provided a *single* article of food for the support of the animal body, she has mingled articles from all the preceding groups. This is the case in *Milk*, which contains of salts nearly equal proportions; of albuminous substance, *casein*, which forms its curd; of *oily* matter, the butter; and of *sugar*, which is dissolved in the whey. The proportions of these vary in the milk of different Mammalia, and they depend in part upon the nature of the food supplied to the Animal that forms the milk; but the substances are thus combined in every instance.

65. It is, however, impossible to measure the value of any particular kind of food for either purpose by a consideration merely of its ultimate or even of its proximate constitution; since its fitness as an article of diet will also depend upon the facility with which it may be reduced by the digestive process, and afterwards assimilated. Thus an aliment abounding in nutritive matter may be inferior to one which really contains a much smaller proportion, if only a part in the first case, and the whole in the second, be readily taken-up by the system. It is obvious that the most *economical* diet will be that in which there is the most perfect apportionment of the several classes of constituents to the wants of the system; and these will vary with the amount of muscular exertion put forth, and with the elevation or depression of the external temperature. Thus, for a man of ordinary habits, and living under a medium temperature, a diet composed of either bread or of animal flesh alone is far from being the most economical. No doubt there are particular conditions of existence under which life may be advantageously supported upon *animal* food alone. Thus the Guachos of South America, who pass the

* Bischoff and Voit, "Gesetze der Ernährung," 1860, p. 215; and see the Report of the French "Gelatine Commission," in the "Compt. Rend.' Août, 1841; that of the Amsterdam Commission in "Het. Institut," No. 2, 1843; "Gazette Médicale," Mars 16, 1844; Voit's Paper in the "Zeitschrift für Biologie," Band viii. 1872, p. 297; and Etzinger idem, Band x. p. 84.

That Gelatin is not destitute of nutritive value is shown by the fact that in one of Bischoff and Voit's experiments a dog, weighing about 80 lbs., lost in four days one pound in body weight when fed with 500 grammes (1 lb. 1 oz. avoird.) of meat alone, but gained in three days 134 grammes (2069 grains) when the same quantity of meat was given together with 200 grammes (3088 grains) of gelatin. That gelatin, even when given in considerable quantities, will not support life, is shown by the results of another experiment, in which a dog weighing over 50 lbs. died on the 31st day when supplied with 3088 grains of gelatin, 2316 grains of starch, 1544 grains of fat, and 185 grains of flesh extract. Etzinger has shown ("Zeits. f. Biologie," B. x.) that ligament, cartilage, and bone, are all largely soluble, with loss of their gelatinifying power, in gastric juice, and are all capable of absorption. Liebig's essence of meat contains from 16—21 per cent. of water, 18—22 per cent. of ash, and 56—60 per cent. of substances soluble in alcohol of 80 per cent. strength and no gelatin or fat. (Thudichum, "On the Origin, Nature, and Uses of Liebig's Extract of Meat," Pamphlet, 1869). In regard to the physiological action of beef-tea and the extract of meat, the reader may refer to the pamphlets on this subject by Kemmerich, Beljawsky, Bogoslowsky ("Centralblatt, f. d. Med. Wiss." No. 32, 1871, and "Archiv f. Anat. u. Phys." 1872); and to Bunge ("Centralblatt," 1871, p. 636). Kemmerich attributed their good effects exclusively to the influence of the alkaline salts they contain, a view that is not supported by the results of experiments performed by other observers.

whole day in the saddle, and lead a life of constant activity resembling that of a carnivorous animal, scarcely ever taste anything but beef; and of this their consumption is by no means great; for the temperature of the surrounding atmosphere is so high that the body has no occasion to generate more heat than is supplied by the combustion of the hydrocarbonaceous portion of the albumen of the food or of "waste" of the tissues. Here, then, the demand for histogenetic material being at its maximum, and that for combustive materials at its minimum, the former supplies all that is requisite for the latter. Again, the Esquimaux and other dwellers upon the Arctic seas find in the bodies of the whales, seals, &c., whereon they subsist, that special supply of the very best combustive material, which alone can enable them to maintain their existence in a climate where the thermometer is for many weeks or months in the year at $-40°$ or even lower, and where the amount of heat which must be generated within the body is four or five times that for which a diet of bread will suffice.—On the other hand, the general experience of the inhabitants of warm climates seems in favour of a diet chiefly or entirely *vegetable;* and its peculiar suitableness appears to consist in its affording an adequate supply of the plastic alimentary substances, in combination with farinaceous matters that give the requisite *bulk* to the food, without affording more combustive material than the system requires,—the quantity of starch which undergoes conversion, and which is introduced as sugar into the circulation, being apparently governed rather by the demands of the respiratory process than by the amount ingested; and the remainder being voided again unchanged.

66. In a well-arranged system of diet the proportion that the non-azotized substances ought to bear to the azotized should be determined by the proportion of Carbon and Nitrogen which are eliminated in the excreta of a healthy man in a given period. Now we know from various experiments that with active exertion about 300 grains of Nitrogen and 4600 grains of Carbon are daily discharged by the several channels of the lungs, skin, kidneys, and bowels; the proportion of the Nitrogen to the Carbon eliminated being, therefore, nearly as 1 : 15. Now, if we compare the composition of bread and of meat, we shall see what is their relative value as aliments, by the proportion which the C holds to the N. According to Payen,* 1000 grains of Bread contain, in round numbers, 300 of Carbon, and 10 of Nitrogen; hence, to obtain the 300 grains of Nitrogen required by the system, 30,000 grains (or more than 4 lbs.) of Bread must be consumed; but the 4600 grains of Carbon required are contained in 15,000 grains of Bread; so that to obtain the requisite supply of Nitrogen a quantity of Bread must be consumed containing exactly double the quantity of Carbon required. Hence it is advantageous to add to a Bread diet a small quantity of Cheese or other highly nitrogenous food. Again, in the case of Meat, 1000 grains contain 100 of Carbon and 30 of Nitrogen; therefore, to obtain the 4600 grains of Carbon, no less than $6\frac{1}{2}$ lbs. must be consumed, whilst the requisite 300 grains of Nitrogen are contained in $1\frac{1}{2}$ lb. of Meat; consequently three or four times more meat must be consumed to supply the Carbon than is necessary to furnish the Nitrogen. The following Table will show how an admixture of bread and meat would require a much less consumption of both than if each were taken separately:—

		Grains of Carbon	*Grains of Nitrogen.*
15,440 grains of	Bread contain	4,630	154
4,630 „	Meat contain	463	154
		5,093	308

* "Des Substances Alimentaires," Paris, 1854.

Thus about 2 lbs. of bread and ¾ lb. of meat are amply sufficient to compensate the daily losses of the system of a healthy man.* Hence we see the immense advantage as to economy of food which a fixed agricultural population possesses over those wandering tribes of hunters which still people a large part both of the Old and New Continents. The *mixed* diet, to which the inclination of man in temperate climates seems usually to lead him (when circumstances allow that inclination to develop itself freely), appears, moreover, to be fully conformable to the construction of his dental and digestive apparatus, as well as to his instinctive propensities. And whilst on the one hand it may be freely conceded to the advocates of "Vegetarianism" that a well-selected vegetable diet is capable of producing (in the greater number of individuals) the highest *physical* development of which they are capable, it may on the other hand be affirmed with equal certainty that the substitution of a moderate proportion of animal flesh is in no way injurious, whilst, so far as our evidence at present extends, this seems rather to favour the highest *mental* development.

67. It is exceedingly difficult to give even an approximation to the composition of the ordinary butchers' meat used as food, since the analyses of different chemists vary considerably; some selecting the muscles alone and the heart, others taking the whole body. The average constitution of entire carcasses of butchers' meat, as given by Messrs. Lawes and Gilbert, the fat being included, is in 1000 parts:—

Animals as fattened for the butcher.	Water.	Dry nitrogenous substance.	Fat.	Mineral matter.
Calf	625	165	166	45
Bullock	500	160	300	50
Lamb	505	110	350	35
Sheep	440	125	400	35
Pig	385	100	500	15

Moleschott gives the following as the composition of the principal animal foods:—

In 1000 parts.	Flesh of Mammals.	Flesh of Birds.	Fish.	Liver.	Eggs.	Milk.
Water	728·75	729·83	740·82	720·06	735·04	861·53
Albuminous compounds	174·22	202·61	137·40	128·20	194·34	39·43
Collagen	31·59	14·00	43·88	37·33	—	—
Fat	37·15	19·46	45·97	35·04	116·37	49·89
Carbohydrates	—	—	—	—	—	43·23
Extractives	16·90	21·11	16·97	65·26	3·74	—
Salts	11·39	12·99	14·96	14·06	10·51	5·92

And the following as representing the composition of the principal Vegetable foods:—

In 1000 parts.	Corn flour.	Legumes (dried peas).	Potatoes.	Beetroot.
Water	150·00	—	760	822·50
Albuminous compounds	132·50	280	10	20·40
Starch	606·80	573	180	—
Sugar, Dextrin	54·80	—	—	122·60
Cellulose	26·60	76	40	25·60
Fat	16·80	—	—	—
Salts	12·50	38	10	8·90

* See Béclard, "Traité Elémentaire de Physiologie," p. 570 *et seq.* 1862. G. Meyer ("Zeits. f. Biol." Band vii. Heft 1) has made a series of interesting observations on the effects of exclusive bread diet on man and dogs. White bread furnished a smaller amount of

According to Dr. Lankester,* 21 oz. of wheat are required to make 1 lb. of flour; and in 1 lb. of flour there are contained—of water $2\frac{1}{4}$ oz., gluten 2 oz., albumen $\frac{1}{4}$ oz., starch $9\frac{1}{2}$ oz., sugar 1 oz., gum $\frac{1}{4}$ oz., fat $\frac{1}{8}$ oz., fibre $\frac{1}{4}$ oz., ashes $\frac{1}{4}$ oz. The carbon contained in 1 lb. of flour amounts to 7 oz. Oysters, which are very digestible and highly nutritious, contain 80·4 parts of water, 14 parts of nitrogenous compounds, 1·5 part of fat, salts 2·7, non-nitrogenous compounds and loss 1·4. According to M. Chevreul, the composition of good beef-tea per litre (1·76 English pint) is:—

Water	985·600
Solid organic substances, dried in vacuo at 68° F.	16·917
Salts	11·263

68. When the results of Experience, then, are combined with the teachings of Science, they seem to justify the following conclusions:—

I. That a due adjustment of the Albuminous, Oleaginous, Saccharine, and Saline constituents of the food, to the varying conditions under which Man exists, is of the first importance; whilst the question of the derivation of the first two of these constituents from the Animal or from the Vegetable kingdom, is one of secondary character; each being capable of yielding them in adequate amount, and the only condition being, that the articles of food shall be so selected as to supply the needful quantity. At the same time it will obviously be requisite that differences should be made in the diet, in accordance with climatic and seasonal variations. For when the external temperature is low an ample supply of oleaginous matter is indicated, and may be advantageously taken in the form of butter, cocoa, fat meat, or maize-bread. On the other hand, during the heat of summer, the more nearly the diet is assimilated to that of the natives of tropical climates, in the substitution of fruits and farinacea for oleaginous articles, the less will be the liability to disordered health in the autumn.†

II. Experience teaches, however, that it is not a matter of entire indifference whether the Albuminous constituent be drawn from the Animal or from the Vegetable kingdom; for the use of a highly animalized diet has a tendency to *raise*, and that of a vegetable diet to *lower*, the proportion of red corpuscles in the Blood; whilst, by a due adjustment of the proportion of the two classes of components, the evil effects of the exclusive use of either may be prevented.

III. So, again, Experience teaches what could scarcely have been anticipated theoretically:—namely, that, notwithstanding the power which the living body possesses of converting saccharine compounds into oleaginous, the

fæces, containing also less nitrogen than Munich rye bread, North German black bread, or the Horsford Liebig's bread, but the feeling of hunger after four days was much greater than with the other kinds of bread. It was found impossible to give sufficient bread to maintain the individual at his full weight, though no less than 94·4 per cent. of the dry material was absorbed. See also Dr. Pavy on the "Physiology and Therapeutics of Food." *Lancet*, 1871–72; and his "Treatise on Food." 1875.

* "Guide to the Food Collection in the South Kensington Museum," p. 39.

† There can be no doubt that a large proportion of the diseases of the digestive apparatus, which are so fatal among European residents in India and other tropical climates, result from the habitual ingestion of a much larger quantity of food, and this especially of a rich and stimulating character, than the system requires. The loss of appetite consequent upon the diminution of the demand for combustive material is set down to the deleterious influence of the climate; and an attempt is made to neutralize this by artificial provocatives.—So, it seems probable that many of the "bilious attacks" which, in this country, are so frequent in early autumn, and which are commonly set down to the account of fruit (although the subjects of them have often abstained entirely from that article), are really the result of the presence of an excess of hydrocarbonaceous matter in the system, consequent upon over-feeding during the summer, and must be looked upon as the natural means by which it is got rid of.

ingestion of a certain amount of Oleaginous matter *as such* is necessary, or at least is favourable, to the maintenance of health. We see this provided in large quantity, in the first aliment prepared by Nature for the offspring of the Mammalia; in the yolk of the egg of all Oviparous animals; whilst, as the laborious investigations of Messrs. Lawes and Gilbert* have shown, the amount of fat contained in ordinary butchers' meat of good quality, to which such a high per-centage of nitrogen is usually attributed, is exceedingly great, varying from one-third to one-half of its weight. In the ordinary diet of every nation on the globe,—whether this be animal, vegetable, or mixed,—we find one or more articles of an oleaginous nature; and there is a natural craving for such substances when they are completely withheld, which indicates that they serve some important purpose in the economy. Although this craving is so far affected by climate that it leads to the largest consumption of oily matter where the extreme of cold has to be endured, it exists with no less intensity even in tropical regions; and we find the Hindoo adding his modicum of "ghee" (or rancid butter made from bisons' milk) to the rice which constitutes his staple article of diet, with the same relish that the Esquimaux feels for his massive lumps of blubber.—It does not seem difficult to understand the *rationale* of this fact. For whilst the Adipose and Nervous tissues are the only portions of the Animal fabric into which fatty matter enters in any considerable proportion, yet its presence has an important influence on the assimilation of albuminous matters, and seems essential to every act of tissue formation. There is strong and increasing reason to believe that a deficiency of oleaginous matter, in a state fit for appropriation by the nutritive processes, is a fertile source of diseased action, especially of that of a tuberculous character: and that the habitual use of it in a larger proportion would operate favourably in the prevention of such maladies, as the employment of cod-liver oil unquestionably does in their cure. A most remarkable example of this is presented by the population of Iceland; which, notwithstanding the concurrence of every one of the circumstances usually considered favourable to the scrofulous diathesis, enjoys a most remarkable immunity from it,—without any other assignable cause than the peculiarly oleaginous character of the diet usually employed.

IV. Another of the results of Experience, of which Science has not yet given a definite *rationale*, is the necessity of employing *fresh vegetables* as an article of Diet; the almost invariable consequence of the entire omission of them being the development of that peculiar constitutional disorder which is known as *Scurvy*.† That the deficiency of something which fresh vegetables can alone supply is the essential cause of this disease (its operation being promoted, however, by other conditions, such as absolute deficiency of food, confinement, bad ventilation, depression of spirits, &c.), may now be regarded as a well-established fact; and it is one which ought to have an important influence on our dietetic arrangements. For if the total withdrawal of these articles be productive of such a fearful depravation of the blood as perverts every function to which the blood is subservient, a diminution of them below the standard requisite for the maintenance of health must necessarily involve a depravation similar in kind though less aggravated in degree; and this, if slight, may be expected to manifest itself, not so much in the production of idiopathic disorders, as in favouring any peculiar tendency to disease which may exist in

* "Phil. Trans." 1859, Pt. ii. p. 495.

† For a full inquiry into this subject, see the "Brit. and For. Med.-Chir. Rev." vol. ii. p. 439.

the system, and in preventing or retarding recovery.* The employment of fresh fruits and of green vegetables seems especially indicated, where a general chronic disorder of nutrition indicates a perverted condition of the circulating material; and especially where there is a disposition to chronic inflammation, induration, and ulceration, in different parts of the body.

v. Finally, then, a well-arranged dietetic scheme ought to consist of such a combination of the Albuminous, Oleaginous, and Farinaceous constituents, as is most appropriate to the requirements of the system;—a larger measure of both the *albuminous* and *farinaceous* or *oily* being supplied, when an unusual amount of nervo-muscular exertion is put forth, and this supply being in the latter case most advantageously derived from animal flesh;—a larger measure of the *oleaginous* being required for the sustentation of the heat in a frigid atmosphere, and this being supplied equally well by the Vegetable kingdom as by the Animal;—and a larger proportion of the *farinaceous*, as a substitute for the oleaginous, being most favourable to health under a high atmospheric temperature. An habitual excess in the use of either of these constituents, above what the demands of the system require, tends towards the production of a particular "diathesis" or constitutional state, which may manifest itself in a great variety of modes. Thus, an excess of the *albuminous* components, such as is only likely to occur when too large a proportion of animal food is employed, undoubtedly favours the *arthritic* diathesis, which seems to consist in the presence of imperfectly-assimilated histogenetic substances and wrongly-metamorphosed products of disintegration, that are not duly eliminated through the kidneys; and this diathesis not only displays itself in gout and gravel, but modifies the course of other diseases. So, again, an excess of the *oleaginous* constituents of the food tends to the production of the *bilious* diathesis, in which, through the insufficient elimination of hydrocarbonaceous matters, the blood becomes charged with the elements of bile. The excess of *farinaceous* matters, moreover, especially when combined with a deficiency of the albuminous (as it too frequently is among those who are obliged by necessity to live chiefly upon a "poor" vegetable diet), tends to the production of the *rheumatic* diathesis; which seems to consist, like the arthritic, in the mal-assimilation and wrong metamorphosis of the components of the tissues, but to be especially favoured by the presence either of lactic acid, or of some other product of the metamorphosis of the saccharine compounds. And, as already pointed out, the deficiency of oleaginous matters seems to tend to the development of the *scrofulous* diathesis; and that of fruits and fresh vegetables to the production of the *scorbutic*.†

* This "scorbutic tendency" was fully recognised by the past generation of Physicians, who practised in those good old times when potatoes were a luxury and green vegetables in the winter almost unknown, when the middle classes fed upon salted meat during a great part of the year, and when sagacious old women prescribed nettle-tea and scurvy-grass, with a course of lenitive "spring-physic," for the "cleansing of the blood."

† It is worthy of remark that in the times when even the wealthy lived during four or five months of the year almost exclusively upon meat, bread, and flour-puddings, and when, therefore, the diet was far too highly-azotized, as well as deficient in fresh vegetables, Arthritic, Calculous, and Scorbutic disorders were much more common than at present. The introduction and universal employment of the potato has unquestionably done much to correct these two tendencies; on the one hand, by diluting the azotized constituents of the food, so that, with the same bulk, a much smaller proportion of these is now introduced; and on the other, by supplying to the blood some element which is essential to the maintenance of its healthy condition. But with the diminution of the Arthritic diathesis, which the experience of our older practitioners, and the medical writings of the last century, indicate as having taken place during that period, there has been an increase in the Rheumatic;—a change which seems to have a close relation to this alteration in diet. And it seems not improbable, too, that this alteration has also much to do with that diminished power of sustaining active

69. The *absolute quantity* of Food required for the maintenance of the Human body in health varies so much with the age, sex, constitution, and habits of the individual, and with the circumstances in which he may be placed, that it would be absurd to attempt to fix any standard which should apply to every particular case. The appetite is the only sure guide for the supply of the wants of each; but its indications must not be misinterpreted. To eat *when* we are hungry is an evidently natural disposition; but to eat *as long as* we are hungry may not always be prudent. Since the feeling of hunger does not depend so much upon the state of fulness or emptiness of the stomach, as upon the condition of the general system, it appears evident that the ingestion of food cannot *at once* produce the effect of dissipating it, though it will do so after a short time; so that, if we eat with undue rapidity, we may continue swallowing food long after we have taken as much as will really be required for the wants of the system; and every superfluous particle is not merely useless, but injurious. Hence, besides its other important ends, the process of thorough mastication is important, as prolonging the meal, and thus giving time to the system to be made acquainted (as it were) that the supply of its wants is in progress; so that its demands may be abated in due time to prevent the ingestion of more than is required. It is very justly remarked by Dr. Beaumont, that the cessation of this demand, rather than the positive sense of satiety, is the proper guide. "There appears to be a sense of perfect intelligence conveyed to the encephalic centre, which, in health, invariably dictates what quantity of aliment (responding to the sense of hunger and its due satisfaction) is naturally required for the purposes of life; and which, if noticed and properly attended to, would prove the most salutary monitor of health, and effectual preventive of disease. It is not the sense of satiety, for this is beyond the point of healthful indulgence, and is Nature's earliest indication of an abuse and overburden of her powers to replenish the system. It occurs immediately previous to this; and may be known by the pleasurable sensations of perfect satisfaction, ease, and quiescence of body and mind. It is when the stomach says, *enough;* and it is distinguished from satiety by the difference of sensations,—the latter saying *too much*." Every medical man is well aware how generally this rule is transgressed; some persons making a regular practice of eating to repletion; and others paying far too little attention to the preliminary operations, and thus ingesting more than is good for them, even though they may actually leave off with an appetite.

70. Although no universal law can be laid down for individuals, it is a matter of much practical importance to be able to form a correct *average* estimate. But even this is given somewhat differently by different observers. Dr. Dalton, for instance,* states that the entire quantity of food required every 24 hours by a man in full health and taking free exercise is, of meat 16 oz. av., bread 19 oz., fat $3\frac{1}{2}$ oz., and of water 52 fl. oz.—that is, about $2\frac{1}{2}$ lbs. of solid food, and rather more than 3 pints of fluid. Vierordt† considers the adult to be well nourished if, with moderate exercise, he receives daily about 4 oz. of

depletory treatment, which, according to the observations of practitioners of long experience characterizes the present generation as compared with the preceding. But whilst there is a diminished capability of bearing large blood-lettings, violent purgation, &c., there is at the same time such an increased tendency to a favourable termination in many of those diseases for which they were formerly accounted necessary, as should remove all regret at this change of constitution.—On the question of "Vegetarianism," the author may refer to his articles on that subject in the "Brit. and For. Med.-Chir. Rev." vol. vi. pp. 76 and 399.

* "Physiology," 1861, p. 97.

† "Grundriss d. Phys.," 1860, p. 192. See also J. Förster, "Zeitsch, f. Biologie," Band ix. 1873, p. 381.

dry albumen, 3 oz. of fat, 11½ oz. of some starchy substance, and about 1 oz. of salts, which gives a proportion of one part of nitrogenous to three and a half parts of non-nitrogenous food. If to this about 6 pints of water, and the oxygen taken up in the act of respiration, which he estimates at 1½ lb., be added, we shall obtain a total of about 1-20th of the weight of the body as the quantity to be ingested in 24 hours. It is from the experience afforded by the usual consumption of food by large bodies of men that our best data are obtained; and these data are sufficient to enable us to predict with tolerable accuracy what will be required by similar aggregations, though they can afford no guide to the consumption of individuals. Parkes and De Chaumont,* who chiefly draw their conclusions from observations made on the diet of soldiers, consider that the standard diet for a male European adult of the average height of 5ft. 6in. to 5ft. 10in., and average weight of 140 to 160 lbs., performing moderate work, may be taken to be 4·5 oz. of dry albuminous substances, 3 oz. of fat, 14 oz. of carbohydrates, and 1 oz. of salts, or 23 oz. of water-free food daily. So that each 1 lb. of body weight receives 0·15 oz., or the whole body receives nearly 1-100th of its weight of dry solids per diem. A certain proportion of water is, however, constantly present, amounting to 50 or 60 per cent., and in addition from 50 to 80 oz. of water are taken in the liquid form; so that on an average 0·5 oz. of water is ingested for each 1 lb. of body weight. Where greater exertion, either mental or bodily, is made, the food must be correspondingly increased in quantity. Thus the average daily water-free diet required for an adult man in very laborious work is—of albuminates, 6 to 7 oz., fats, 3·5 to 4·5 oz., carbohydrates, 16 to 18 oz., salts, 1·2 to 1·5 oz., with a large addition to the quantity of water to compensate for the increased loss by evaporation from the skin and lungs. Great variations of course occur consequent on differences of size and weight as well as upon activity of the organic functions.

The information collected by Dr. Edward Smith for the Government,† showed, indeed, that some people eat ten times more food, in point of nutriment, than others, and that in whole classes of the community a difference of one-half in the amount obtained by the lowest fed is common. From the extended experiments he made on the amount of Carbon daily eliminated by men in good health during the middle period of life when at perfect rest, it appeared that it amounts to 7·9 oz., with the estimated exertion of the middle and light labouring classes to 9·5 oz., and with the estimated exertion of the hard labouring classes to 12·5 ounces. On an examination of the nature of the food actually consumed by these classes, it was found that the proportion of Carbon present was approximately represented by the above numbers; indoor labourers, as cotton and silk operatives, needle-women, and shoemakers, consuming about 10·5 oz., and agricultural labourers in England, 13·2 oz.; in Great Britain and Ireland, 14·1 oz. Hence it may be stated that the adult body requires an average minimum daily amount of Carbon of 9½ to 10½ ounces in the middle and light labouring classes, and of 12½ to 14 ounces in the ordinary hard labouring classes, that is from 25 to 30 grains per lb. weight of the whole body. It is interesting to notice that the infant consumes no less than 136 grains of Carbon for each pound of body weight, a proportion three to four times greater than that actually obtained by the poor in adult life. As regards the amount of Nitrogen, Dr. Smith's observations showed that about 200 grains of Nitrogen are used up daily in the working of the body by the light labouring classes, whilst in the middle and well-fed

* Parkes, "Practical Hygiene," 5th edit., edited by De Chaumont, 1878, p. 192. See also Pavey, "Treatise on Food," 1875, p. 458. † See "Practical Dietary," 1864, p. 20.

classes the total evacuation by all the excretions was 260 grains. The actual amount obtained in food by the indoor classes was 183 grains, and by the outdoor labourers in England 242 grains; and hence we may place the supply of the adult body daily at 200 grains with light occupation, and 250 grains for ordinarily hard working labourers, or from 1 to 1½ grain per lb. of body weight. This quantity is, however, undoubtedly insufficient for the maintenance of thoroughly sound health; and the proportions already given of 300 grains of nitrogen, and 4000 or 4500 grains of carbon with 460 grains of salts, are those which experience indicates as best fulfilling the requirements of the body in the case of a healthy adult with moderately active exertion. The proportion of nitrogen to carbon in such a diet is as 1:15, or expressing it in another way, if the proportions of nitrogenous substances in a standard diet be taken as 1, the fats should be ·6, the carbohydrates 3, and the salts 1·5. In the infant at the breast the proportion of nitrogen consumed to the body weight is stated by Dr. Smith to be six times as great as in the adult. The salts seem to be made up of chlorine 120 grains, phosphoric acid 50 grains, potash 40, soda 40, lime about 4 grains by the urine and some by the bowels, magnesia 4·7 grains by the urine, and a considerable amount by the bowels and iron, the amount of which is uncertain. The following is a dietary furnished by Dr. Smith,* which he considered may be taken as the substantial part of a proper and moderate quantity of food for a man in good health with a good appetite, and making a moderate degree of exertion:—*Breakfast.*—¾ pint of milk; ¼ pint of water with coffee or tea; bread, 4 oz. to 6 oz.; butter, ¾ oz.; sugar, ¾ oz.; bacon, 3 oz., or eggs, 4 oz., or cooked meat, 3 oz. *Dinner.*—Cooked meat, 4 oz. to 6 oz.; potatoes, 8 oz.; bread, 3 oz. to 4 oz.; pudding, 8 oz.; cheese, ½ oz.; soup, 6 oz.; water or beer, ½ pint. *Tea.*—Water with tea, ¾ pint; sugar, ¾ oz.; milk or cream, 2 oz.; bread, 3 oz.; butter, ½ to ¾ oz. *Supper.*—Milk, ¾ pint; oatmeal, 1 oz., and bread 3 oz. to 4 oz., or eggs, 4 oz., or cooked meat, 3 oz., and bread, 3 oz.; butter or cheese, ½ oz.; water or beer.

In the case of Prisoners, the diet should be, of course, as spare as possible, consistently with health; but it should be carefully modified, in individual cases, according to several collateral circumstances, such as depression of mind, compulsory labour, previous intemperate habits, and especially the length of confinement. It has been supposed by some that prisoners require a fuller diet than persons at large; this is probably erroneous; but some variety is certainly desirable to counteract, as far as possible, the depressing influence of their condition upon the digestive powers. The evil effect of an undue reduction in the supply of food, and of insufficient attention to its quality, has unfortunately been too frequently displayed in our prisons; a notable example of which will be hereafter alluded to (§ 81).

71. The smallest quantity of food upon which life is known to have been supported with vigour during a prolonged period, is that on which Cornaro states himself to have subsisted; this was no more than 12 oz. a day, chiefly of vegetable matter, with 14 oz. of light wine, for a period of 58 years. There is another well-known case (that of Thomas Wood, the miller of Billericay, reported to the College of Physicians in 1767 by Sir George Baker), in which a remarkable degree of vigour was sustained for upwards of eighteen years, upon no other nutriment than 16 oz. of flour (containing about 14 oz. of *dry* solids) made into a pudding with water, no other liquid of any kind being taken. There are probably few, however,—at least among those whose avocations require much mental or bodily exertion,—who could long

* For numerous other dietaries, see Pavy, "A Treatise on Food," 1874.

persevere in such a diet. Still it is certain that life with a moderate amount of vigour may be preserved for some time on a very limited allowance of food; this appears from the records of shipwreck and similar disasters. In regard, however, to those who have been stated to fast for a period of months or even years, taking no nutriment, but maintaining an active condition, it may be safely asserted that they were impostors, probably possessing unusual powers of abstinence which they took means to magnify.

72. Of the quantity which *can* be devoured at one time, this is scarcely the place to speak; since such feats of gluttony only demonstrate the extraordinary capacity which the stomach may be made to attain by continual practice. Many amusing instances are related by Captain Parry in his "Arctic Voyages;" in one case a young Esquimaux, to whom he had given (for the sake of curiosity) his full tether, devoured in four-and-twenty hours no less than 35 lbs. of various kinds of aliment, including tallow candles. A case has more recently been published of a Hindoo who can eat a whole sheep at a time; this probably surpasses any other instance on record. The half-breed *voyageurs* of Canada, according to Sir John Franklin, and the wandering Cossacks of Siberia, as testified by Capt. Cochrane, habitually devour a quantity of animal food which would be soon fatal to any one unused to it. The former are spoken of as very discontented when put on a short allowance of 8 lbs. of meat a day; their usual consumption being from 12 to 20 lbs.—That a much larger quantity of food than that formerly specified may be habitually taken with perfect freedom from injurious consequences, under a particular system of exercise, &c., appears from the experience of those who are *trained* for feats of strength, pugilistic encounters, &c. The ordinary belief that the Athletic constitution cannot be long maintained appears to have no real foundation; nor does it appear that any ultimate injury results from the system being persevered-in for some time. That "trained" men often fall into bad health on the cessation of the plan, is probably owing in part to the intemperance and other bad habits of persons of the class usually subjected to this discipline. The effects of trainers' regimen are hardness and firmness of the muscles, clearness of the skin, capability of bearing continued severe exercise, and a feeling of freedom and lightness (or "corkiness") in the limbs. During the continuance of the system, it is found that the body recovers with wonderful facility from the effects of injuries; wounds heal very rapidly; cutaneous eruptions usually disappear. Clearness and vigour of mind, also, are stated to be results of this plan.* The injurious effects observed in those who suddenly engage in trials of strength and endurance, as in rowing, running, and gymnastics, are probably attributable to their being undertaken by young persons who have undergone an insufficient amount of training, and who exhaust themselves by exerting their whole nervous ener-

* The method of training employed by Jackson (a celebrated trainer of prize-fighters in modern times), as deduced from his answers to questions put to him by John Bell, was to begin on a clear foundation by an emetic and two or three purges. Beef and mutton, the lean of fat meat being preferred, constituted the principal food; veal, lamb, and pork were said to be less digestible ("the last purges some men"). Fish was said to be a "watery kind of diet:" and is employed by jockeys who wish to reduce weight by sweating. Stale bread was the only vegetable food allowed. The quantity of fluid permitted was 3½ pints *per diem;* but fermented liquors were strictly forbidden. Two full meals, with a light supper, were usually taken. The quantity of exercise employed was very considerable, and such as few men of ordinary strength could endure.—This account corresponds very much with that which Hunter gave of the North American Indians, when about to set forth on a long march. Playfair gives the diet of a prize-fighter in training as 9·8 oz. albuminates, 3·1 fats, and 3·27 starch and sugar. There were 690 grains of nitrogen, and 4366 grains of carbon.

gies, or who induce some physical derangement of the vascular or respiratory system, by the violent muscular efforts put forth.*

73. It is not enough for the healthy support of the body that the Food ingested should contain an adequate proportion of alimentary constituents; it is important that these should be in a wholesome or undecomposing state. That meat which is simply putrescent is to be considered as injurious *per se*, when habitually employed, is scarcely a matter of reasonable doubt. It is true that some nations are in the habit of keeping their meat until it is tainted, having a preference for it in that condition, which seems to have grown out of the supposed necessity for thus employing it; a preference which has its parallel among the epicures in our own country, who consider the *haut goût* essential to the perfection of their venison or woodcock. One of the most remarkable examples of this kind among a civilized people is furnished by the inhabitants of the Färoe Islands, who, according to the report of Dr. Panum, who has investigated their Sanitary condition, live during a large part of the year upon meat in a state of incipient decomposition, and introduce *rast*, or half-decayed maggoty flesh, fowl, or fish, as a special relish at the end of a meal.† The result of such a diet is (as might be anticipated) a continual disorder of the digestive organs, manifesting itself especially by diarrhœa, which also complicates the course of other diseases, and even becomes, from its obstinacy and exhausting character, their most serious complication. Moreover, the Färoese are peculiarly liable to suffer severely from epidemics, when these are introduced among them. Hence, notwithstanding that the usual rate of mortality is very low (only 1 in $64\frac{2}{3}$ annually), it is obvious that there is a certain constitutional condition among them which peculiarly favours the reception and propagation of zymotic poisons; and it is quite conformable to the principles elsewhere laid down, to attribute this to the habitual introduction of putrescent matter with the food. It is probable, indeed, that if it were not for the active lives of the Färoese, and their habitual exposure to a low external temperature, the direct effects of their diet would be far more prejudicial than they are; but a large part of these are probably neutralized by that activity of respiration which the habits of life of this hardy people induce, much of the noxious matter being decomposed and eliminated by the combustive process. Hence it may well be conceived that the effects of putrescent food would be much more decidedly manifested amongst individuals dwelling in close, ill-ventilated apartments: and although the same means of comparison do not exist, since there is no part of our town-population habitually subsisting on such a diet as that of the Färoese, yet there is no want of evidence with regard to the injurious effects of even the occasional employment of putrescent food, especially when any zymotic disease is epidemic.

74. That it is Water which constitutes the natural drink of Man, and that no other liquor can supply its place, is apparent from the most cursory glance at its uses in the system; and it is only necessary here to remark, that the purity of the water habitually ingested is a point of extreme importance. A very minute impregnation with lead, for example, is quite sufficient to develop all the symptoms of chronic lead-poisoning, if the use of such water be sufficiently prolonged. In the case of the ex-royal family of France, many

* See Skey's Letter and subsequent discussion in "Times" of October, 1867.

† See Dr. Panum's 'Observations on an Epidemic of Measles in the Färoe Islands,' in the "Bibliothek for Lægr." 1846; of which an analysis is given in the "Brit. and For. Med.-Chir. Rev." vol. vii. p. 419.

of whom suffered in this manner at Claremont,* the amount of lead was only about one grain per gallon; and in a case subsequently published, in which also the symptoms of lead-poisoning were unequivocally developed, the amount was no more than 1-9th of a grain.† So, again, an excess of the saline ingredients which appear to be innocuous in small quantities, may produce a marked disorder of the digestive organs, and (through them) of the system generally.‡ Moreover, as in the case of food, the presence of a very small amount of putrescent matter is quite sufficient to produce the most pernicious results, when that matter is habitually introduced into the system; and these results, on the one hand, manifest themselves in the production of certain disorders which appear distinctly traceable to the direct action of the poison so introduced; whilst, on the other, they become apparent in the extraordinary augmentation of the liability to attacks of such zymotic diseases as may at the time be prevalent.§ The quantity of water daily consumed is from 3 to 5 pounds; and a slight excess, indicative of its formation in the system, is daily eliminated. The ingestion of large quantities has been shown by Mosler‖ to cause a considerable increase in the discharge of urea and salts in the urine, which appears to be the result of an increased metamorphosis of the albuminous constituents of the blood and tissues. The quantity of alcoholic liquids consumed in the United Kingdom is extraordinarily great. A recent writer (Mr. W. Hoyle)¶ states that in 1878 29,358,715 gallons of home spirits; 10,438,637 gallons of foreign spirits; 16,272,295 gallons of wine; 1,117,316,754 gallons of beer; and about 17,500,000 gallons of cider and British wine were consumed. The proportion of Alcohol in beer varies from 1 to 12 per cent.; in the light wines of France and Germany from 8 to 15 per cent., and in the stronger Spanish wines from 15 to 25 per cent. Besides Alcohol, all wines contain certain volatile Ethers, and more or less of the Acetic, Tartaric, and Tannic Acids. Sugar and Extractives are also commonly present. The use of *Alcohol*, in combination with water and with organic and saline compounds, in the various forms of "fermented liquors," deserves particular notice, on account of the numerous fallacies which are in vogue respecting it.—In the *first* place, it may be safely affirmed that Alcohol cannot answer any one of those important purposes for which the use of Water is required in the system; and that, on the other hand, it tends to antagonize many of those purposes, by its power of precipitating most of the organic compounds, whose solution in water is essential to their appropriation by the living body. *Secondly*, the ingestion of alcoholic liquors cannot supply anything which is essential to the due nutrition of the system; since we find not only individuals, but whole nations maintaining the highest vigour and activity, both of body and mind, without ever employing them as an article of diet. *Thirdly*, there is no reason to believe that Alcohol, in any of its forms, can become directly subservient to the nutrition of the tissues; for it may be certainly affirmed that in common with non-azotized substances in general, it is incapable of transformation into albuminous compounds; and there is no sufficient evidence that even Fatty matters can be generated in the body at

* See the account of this case, which presents many features of great interest, in the "Dublin Quarterly Journal of Medical Science," vol. vii. p. 415.

† See Herapath in "Medical Gazette," Sept. 20, 1850, p. 518.

‡ Of this a very instructive case, which occurred at Wolverton, has been published by Mr. Corfe in the "Pharmaceutical Journal," July, 1848.

§ For ample evidence to this effect, see Dr. Pereira's "Treatise on Food and Diet," pp. 89–91; and the "Report of the General Board of Health on the Epidemic Cholera of 1848 and 1859," pp. 59–63, "Appendix A," p. 14, and "Appendix B," pp. 91–95.

‖ "Archiv des Vereins f. gemeins Arbeit.," Band iii. 1857, p. 398.

¶ "Times," March 11th, 1879.

its expense. *Fourthly*, the operation of Alcohol upon the living body is essentially that of a *stimulus;* increasing for a time, like other stimuli, the vital activity of the body, and especially that of the nervo-muscular apparatus, so that a greater effect may often be produced in a given time under its use than can be obtained without it; but being followed by a corresponding depression of power, which is the more prolonged and severe in proportion as the previous excitement has been greater. The experiments of Anstie and Dupré show that when Alcohol is consumed in moderate quantities, as of two ounces in divided doses, in the course of the day, the merest traces only are eliminated by the excretions. There can be little doubt, therefore, that it undergoes oxidization in the system.* M. Dupré has shown that weight for weight Alcohol evolves about four times the amount of heat or actual energy that is evolved by lean beef.† Yet other researches‡ show that Alcohol in tolerably full doses lowers the temperature of the body, although it increases the force and frequency of the pulse; and the experience of Arctic voyagers is *most decided* in regard to the comparatively low value of Alcohol as a heat-producing material. It is certain that Alcohol is not without its value under certain circumstances; and the views expressed by Dr. Hammond,§ that its effects, injurious or salutary, are in a great measure dependent upon the quantity of food consumed with it, are probably true. When the food is ample in quantity and varied in quality, and the digestion good, Alcohol is unnecessary, exciting the circulation, and tending to produce a plethoric condition of the system; but when the diet is insufficient, or the digestion feeble, the effects of Alcohol, when taken in moderate quantities, seem decidedly beneficial, the body not only ceasing to lose, but actually gaining in weight; the Alcohol either taking the place of the food, or retarding the metamorphosis of the tissues. In conditions of exhaustion it often proves of the greatest utility, and there is reason for believing that it can exert an antiseptic power in certain states of blood poisoning, whilst it exerts a powerful influence over the formation of pus in inflamed parts; partly perhaps by restraining the movements of the white corpuscles of the blood, partly by hardening the walls of the vessels and preventing their escape, and partly by its general power of lessening tissue change and cell-genesis. The Physiological objections to the habitual use of Alcoholic liquors rest upon the following grounds:—*First*, they are universally admitted to possess a *poisonous* character, exhibited when they are taken in tolerably large doses by loss of appetite and diminished muscular power and control over the voluntary movements, with partial paralysis of the sympathetic nervous system, leading to dilatation of the

* And this accounts for the fact that some persons who consume large quantities of fermented liquors become very fat; the hydrocarbonaceous matters in the system being prevented from undergoing the combustive process to which they would otherwise be subject. Much of the fatty deposit in intemperate persons has the character of "fatty degeneration;" the tendency to which is very marked in persons of this class.

† MM. Duroy, Lallemand, and Perrin, "Du rôle de l'Alcool et des Anesthétiques dans l'Organisme," 1860, Dr. Marcet, "Chronic Alcoholic Intoxication," 1862, and Dr. E. Smith, "Cyclical Changes," and more recently Dr. Ssubotin, "Zeitschrift fur Biologie," Band vii. 1871, p. 361, thought that a considerable quantity of the alcohol ingested was discharged unchanged; but as Anstie and Dupré have shown in their papers in the *Lancet*, 1865, and *Practitioner*, 1872, 1873—in which references will be found to the principal authors on this interesting subject—this view arose either from erroneous observations and inefficient mode of testing for alcohol, or to very large doses being administered to small animals like the rabbit, in which case no doubt a considerable quantity is eliminated unchanged. See also in relation to this subject Dr. Richardson, "Reports Brit. Assoc." 1864 and 1869; Schulinus, "Archiv. f. Heilk.," 1866; Parkes and Wollowicz, "Proc. Roy. Soc. 1870;" Schmidt, "Centralblatt," 1875, p. 371.

‡ Ringer, *Lancet*, 1866, vol. ii. p. 208. § "Amer. Journ. of Med. Sciences," Oct. 1856.

smaller vessels; whilst death is the speedy result of very large doses through the suspension of nervous power, which their introduction into the circulation in sufficient quantity is certain to induce. *Secondly*, when habitually used in excessive quantities, universal experience shows that Alcoholic liquors tend to produce a morbid condition of the body at large, and especially of the nervous system; this condition being such as a knowledge of its *modus operandi* on the body would lead the Physiologist to predicate. *Thirdly*, the frequent occurrence of more chronic diseases of the same character, among persons advanced in life, who have habitually made use of Alcoholic liquors in "moderate" amount, affords a strong probability that they result from a gradual perversion of the nutritive processes, of which that habit is the cause. This perversion manifests itself peculiarly in the tendency to "fatty degeneration" of the muscular substance of the heart, of the walls of the arteries, of the glandular substance of the kidney and liver, and of many other parts; and thus gives rise to a great variety of forms of disease. *Fourthly*, the special liability of the intemperate to zymotic diseases seems an indication that the *habitual* ingestion of Alcoholic liquors tends to prevent the due elimination of the azotized products of the disintegration of the system, and thus to induce a "fermentible" condition of the blood. *Fifthly*, extended experience has shown that, notwithstanding the temporary augmentation of power which may result from the occasional use of fermented liquors, the capacity for prolonged endurance of mental or bodily labour, and for resisting the extremes of heat and cold, as well as other depressing agencies, is diminished rather than increased by their habitual employment; and the reason of this, so far as cold is concerned, is sufficiently obvious. Under ordinary circumstances of exposure to cold the circulation of blood through the vessels of the surface, owing to the contraction of the cutaneous capillaries, is greatly reduced, and much less heat is lost by conduction and radiation, the skin alone being a very bad conductor.* When, however, considerable quantities of Alcohol are taken, more or less complete paralysis of the vaso-motor nervous system is the result: the vessels of the skin no longer respond to the stimulus of cold, and the blood traversing them loses a large amount of heat; so that whilst in all instances where the quantity of Alcohol consumed exceeds the moderate limits of 1½—2 oz. per diem, there is diminished power of resistance to cold, this is felt much more acutely in extreme cases, and death may even take place from the general reduction of the temperature.† On these grounds, the Author has felt himself fully justified in the conclusion that, for Physiological reasons alone, habitual abstinence from Alcoholic liquors is the best rule that can be laid down for the great majority of healthy individuals; the exceptional cases in which any real benefit can be derived from their use being comparatively few.‡

75. The very extensive employment of Tobacco by men of almost every rank in society in this country, and the large consumption of Tea and Coffee by both sexes throughout the community, render the study of their effects upon the animal economy particularly interesting, though up to the present time exceedingly few observations have been made. The effects of Tobacco are chiefly due to the absorption of the extremely poisonous liquid alkaloid Nicotin,§ which exists in the plant in combination with Citric and Malic acids,

* See Klug, "Zeits. f. Biologie," Band x. 1874, p. 73.

† A very remarkable example of the effects of cold on whisky and non-whisky drinkers is recorded in the *Lancet*, vol. i. 1871, p. 636.

‡ See his "Physiology of Temperance and Total Abstinence;" also the important Treatise on "Alcoholismus Chronicus," by Dr. Huss of Stockholm, of which an abstract is given in the "Brit. and For. Med.-Chir. Rev." vols. vii. and ix.

§ See Heubel, "Exp. Beiträge," "Centralblatt f. d. Med. Wiss." 1872, p. 641.

and from its remarkable volatility, is contained in and inhaled with the smoke of the smouldering leaves. Its chemical composition is represented by the formula $C_{10}H_{14}N_2$. Dr. Hammond's conclusions (Op. cit.) from his experiments upon the use of Tobacco are, that whilst it only slightly affects the excretion of carbonic acid from the lungs, it diminishes the quantity of fæces, urine, aqueous vapour, and of chlorine, but it increases the amount of uric, phosphoric, and sulphuric acids eliminated by the kidneys,—circumstances which seem to indicate that there is an increase in the interstitial changes taking place in the brain and nervous tissue, of which there are other indubitable signs, as wakefulness, trembling, and nervous excitement. The quantity employed in the experiment was two cigars thrice a day.—These results accord with general experience; and there are few who will not coincide with the remarks made by Sir B. Brodie in a letter to the "Times" on this subject, dated Aug. 27th, 1860, in which he observes that when used in limited quantity, and under circumstances of privation, Tobacco may be not only harmless but absolutely beneficial by soothing and tranquillizing the nervous system, allaying hunger and the uneasy feelings produced by mental and bodily exhaustion; but that in too many instances it is only a bad habit, producing a greater or less degree of derangement of the nervous system, and indisposing to both mental and bodily exertion. Tea and Coffee, though derived from different classes of the Vegetable kingdom, appear to contain nearly the same organic constituents, but in different proportions. In making "Tea" and "Coffee," the Theine, Gum, Sugar, and Tannic Acids they contain are chiefly extracted, whilst the Casein, unless a little soda be added to the water, remains undissolved. It is a singular circumstance that the Alkaloid contained in Tea and Coffee, as well as that in Maté, the shrub used for tea in Paraguay, should have the same chemical composition ($C_8H_{10}N_4O_6 + 2$ Aq.). Strong decoctions of both fluids counteract the tendency to sleep, excite the nervous system and heart, and produce contractions and tremors in the muscles.* Tea is a respiratory excitant while coffee depresses this function. Lehmann† and Böcker‡ consider that tea and coffee diminish the excretion of urea, and consequently the disintegration of the albuminous tissues, whilst they effect an increase in the amount of water discharged. Voit,§ however, from observations on a dog, and Squarey‖ from experiments on men, conclude that coffee possesses little or no influence on the general nutrition of the body.

2. *Of Hunger and Thirst;—Starvation.*

76. The want of solid Aliment, arising from the demands of the system for the materials requisite for the growth and maintenance of the body, and for the combustive process, is indicated by the sensation of Hunger; and that of liquid, by Thirst. The former of these sensations is referred to the stomach, and the latter to the fauces; but although certain conditions of these parts may be the immediate cause of the sensations in question, they are really indicative of the requirements of the system at large. For the intensity of the feeling bears no constant relation to the amount of solid or liquid aliment in the stomach; whilst, on the other hand, it does correspond with the excess of demand in the system, over the supply afforded by the blood; and it is

* See M. Leven in Brown-Sequard's "Archives de Physiologie," t. i. p. 179.

‖ See Dr. Parkes' "Practical Hygiene," 5th edit. p. 309, note.

caused to abate by the introduction of the requisite material into the circulating fluid, even though this be not accomplished in the usual manner by the ingestion of food or drink into the stomach.

77. That the sense of hunger, however, is *immediately* dependent upon some condition of the Stomach seems to follow from the fact, that it may be temporarily alleviated by introducing into the digestive cavity matter which is not alimentary. Of the precise nature of that condition, we have no certain knowledge. It is easy to prove that many of the causes which have been assigned for the sensation, are but little, if at all, concerned in producing it. Thus, mere emptiness of the stomach cannot occasion it; since, if the previous meal have been ample, the food passes from its cavity some time before the uneasy feeling is renewed; and this emptiness may continue (in certain disordered states of the system) for many hours, or even days, without a return of desire for food. Besides, the stomach may be filled with food, and yet Hunger may be intensely felt, if, from disease of the pylorus or any other cause, there be an obstacle to the passage of the aliment into the intestine, and to the completion of the processes of chylification and absorption, so that the system needs that which the digestive apparatus is unable to provide for it. Again, the sense of Hunger cannot be due, as some have supposed, to the action of the gastric fluid upon the coats of the stomach themselves; since this fluid is not poured into the stomach, except when its production is stimulated by the irritation of the secreting follicles. Nor is it conveyed through the pneumogastric nerves, since, as shown by Dr. John Reid,* after section of these nerves animals take food with no less avidity than previously; indeed, the sense of satiety rather than that of Hunger seems to be abolished, the animals often continuing to gorge themselves with food long after the Stomach has been adequately filled.—It may, perhaps, be a more probable supposition that there is a certain condition of the Capillary circulation in the Stomach, which is preparatory to the secretion, and which is excited by the influence of the Sympathetic nerves, that communicate (as it were) the wants of the general system. This condition may be easily imagined to be the proximate cause of the sensation of hunger, by acting on the nervous centres. When food is introduced into the stomach, the act of secretion is directly excited; the capillary vessels are gradually unloaded; and the immediate cause of the impression on the nervous system is withdrawn.† By the conversion of the alimentary matter into materials fit for the nutrition of the system, the remote demand also is satisfied; and thus it is, that the condition of the stomach just referred-to, is permanently relieved by the ingestion of substances that can serve as food. But if the ingested matter be not of a kind capable of solution and assimilation, or the digestive apparatus cannot effect its preparation, the feeling of hunger is only temporarily relieved, and soon returns in greater force than before.—The theory here given seems reconcilable with all that has been said of the conditions of the sense of Hunger; and particularly with what is known of the effect produced upon it by nervous impressions, which have a peculiar influence upon the capillary circulation. It also corresponds exactly with what we know of the influence of the nervous system, and of mental impressions, upon other secretions (CHAP. XVII.).

78. The sense of Hunger, like other sensations, may not be taken cognizance of by the mind, if its attention be strongly directed towards other objects; of this fact, almost every one engaged in active operations, whether mental or

* "Phys. Anat. and Pathol. Researches," pp. 234—239.

† These views seem to be confirmed by the observations of M. Bernard on the condition of the gastric follicles during the intervals of their functional activity.

bodily, is occasionally conscious. The nocturnal student, who takes a light and early evening meal, and, after devoting himself to his pursuits for several hours uninterruptedly, retires to rest with a wearied head and empty stomach, but without the least sensation of hunger, is frequently prevented from sleeping by an indescribable feeling of restlessness and *deficiency;* and the introduction of a small quantity of food into the stomach will almost instantaneously allay this, and procure comfortable rest. Many persons, again, who desire to take active exercise before breakfast, are prevented from doing so by the lassitude and even faintness which it induces,—the bodily exercise increasing the demand for food, whilst it draws-off the attention from the sensation of hunger.

79. The conditions of the sense of Thirst appear to be very analogous to those of hunger. This sense is not referred, however, to the stomach, but to the fauces. It is probably even more immediately connected with the state of the general system, than that of hunger: for the immediate relief afforded by the introduction of liquid into the stomach is fully accounted-for by the instantaneous absorption of the fluid into the veins, which is well known to take place when there is a demand for it. This demand is increased with almost equal rapidity, by an excess in the amount of the fluid excretions; and it may be satisfied, or at least alleviated, without the introduction of water into the stomach, this having been one of the results observed after the use of saline injections into the veins in cases of Asiatic Cholera, as well as after immersion in a warm bath in cases of extreme dysphagia. Thirst may also be produced, however, by the impression made by peculiar kinds of food or drink upon the walls of the alimentary canal; thus salted or highly-spiced meat, fermented liquors when too little diluted, and other similarly irritating agents, excite thirst; the purpose of which is obviously to cause ingestion of fluid by which they may be diluted.

80. The results of an entire deficiency of Food, or of its supply in a measure inadequate for the wants of the system, constitute the phenomena of *Inanition* or *Starvation.* These have been experimentally studied by M. Chossat* on Birds and Mammals; and the information thence gained leads us to a better comprehension of what is (unfortunately) too frequently exhibited in the Human subject.—The following were the general symptoms noted by M. Chossat:—The animals usually remain calm during the first half or two-thirds of the period; but they then become more or less agitated; and this state continues as long as their temperature remains elevated. On the last day of life, however, whilst the temperature rapidly falls, this restlessness ceases, and gives place to a state of stupor. The animal, when set at liberty, sometimes looks round with astonishment, without attempting to fly; and sometimes closes the eyes, as if in a state of sleep. Gradually the extremities become cold, and the limbs so weak as no longer to be able to sustain the animal in a standing posture; it falls over on one side, and remains in any position in which it may be placed, without attempting to move. The respirations become slower and slower; the amount of urea eliminated diminishes, at first suddenly, and then more slowly, indicating reduced disintegration of the albumins of the blood and tissues; the general weakness increases, and the insensibility becomes more profound; the pupil dilates; and life becomes extinct, sometimes in a calm and tranquil manner, sometimes after convulsive actions producing opisthotonic rigidity of the body. After the first day, in which the fæces contain the residue of the food previously taken, their amount is very small; and they seem to

* "Recherches Expérimentales sur l'Inanition," Paris, 1843. See also Panum, Virchow's "Archiv," Band xxix. p. 241; and Voit, "Zeitschrift f. Biologie," Band ii. p. 307.

consist principally of grass-green biliary matter. Towards the close of life they contain a much larger quantity of water, even when none has been ingested by the animal; and include much saline matter in addition to the biliary.—The average loss of weight in the warm-blooded animals experimented-on by M. Chossat, between the commencement of the period of Inanition and its termination by death, was 40 per cent.; but he met with a considerable variation in the extremes, which seemed to depend chiefly on the amount of fat previously accumulated in the body; those animals losing most weight in which the fat had been most abundant, which were also those that lived the longest.* Taking 40 per cent. as the mean, M. Chossat obtained the following curious results as regards the relative diminution of the several tissues and organs of the body; those which lost *more* than the mean being distinguished from those which lost *less*.

Parts which lose *more* than 40 per cent.		Parts which lose *less* than 40 per cent.	
Fat	93·3	Muscular coat of stomach	39·7
Blood	75·0	Pharynx and œsophagus	34·2
Spleen	71·4	Skin	33·3
Pancreas	64·1	Kidneys	31·9
Liver	52·0†	Respiratory apparatus	22·2
Heart	44·8	Osseous system	16·7
Intestines	42·4	Eyes	10·0
Muscles of locomotion	42·3	Nervous system	1·9

The points most worthy of note in the above Table, are the almost complete removal of the *fat*, and the reduction of the *blood* to three-fourths its normal amount, the diminution, as has since been shown by Valentin and Panum, especially affecting the albumen of the serum; whilst the *nervous system* undergoes scarcely any loss. It would seem, in fact, as if the supervention of death was coincident with the consumption of all the disposable combustive material: and that up to that point, the whole remaining energy of nutrition is concentrated upon the nervous system. And it will be shown hereafter that there is adequate ground for considering death by *starvation* as really death by *cold;* since the temperature of the body is maintained with little diminution until the fat is thus consumed, and then rapidly falls, unless it be kept up by heat externally applied.—As might be expected from the comparative rapidity of interstitial change at the earlier periods of life, it was found by Chossat that the diurnal loss was much the most rapid in young animals, and that the duration of their lives when deprived of food was consequently far less than that of adults. He further ascertained that the results of *insufficient* alimentation were in the end the same as those of entire deprivation of food; the total amount of loss being almost exactly identical, but its rate being less, so that a longer time was required to produce it. Neither he nor Scheffer‡ found that much influence was exerted on the duration of life, by permitting or withdrawing the supply of water; the latter experimenter found that in a dog wholly deprived of water the loss in weight of the different organs was nearly the same as in deprivation of solid food, with the exception of the brain, fat

* There is a well-known case of a fat pig, which was buried in its sty for 160 days, under thirty feet of the chalk of Dover cliff, and which was dug out alive at the end of that time, reduced in weight from 160 lbs. to 40 lbs., or no less than 75 per cent. ("Trans. of Linn. Soc.," vol. xi. p. 411). This extraordinary prolongation of life in this case may be attributed to the retention of the *heat* of the body by the non-conducting power of the chalk, and to the retention of its *moisture* by the saturation of the air in its immediate vicinity, and restriction of its movements.

† Bidder and Schmidt found that the liver of a cat lost about two-thirds of its original weight, and Voit arrived at the same conclusion in the case of a dog.

‡ Ludwig, "Physiologie," 1861, vol. ii. p. 683.

and glandular organs, which were not materially diminished. All the tissues became much drier; the skin, tendons, muscles, intestines, and blood, containing from 4–11 per cent. more solid residue than in health. It appears, however, that in Man death supervenes much earlier when liquid as well as solid aliment is withheld; and the indifference observed by Chossat in the case of Birds is probably due to the fact that they ordinarily drink very sparingly, and eliminate very little water in their various secretions. If absolutely dry food be given, most animals after a short time cease to eat. The experiments of Blundell and Panum show that the life of a dog deprived of food cannot be preserved by the frequent transfusion of the blood of other healthy dogs.

81. The most prominent symptoms of Starvation, as they have been noted in the Human subject, are as follows:—In the first place, severe pain in the epigastrium, which is relieved on pressure; this subsides after a day or two, but is succeeded by a feeling of weakness and "sinking" in the same region; and an insatiable thirst supervenes, which, if water be withheld, thenceforth becomes the most distressing symptom. The countenance becomes pale and cadaverous; the eyes acquire a peculiar wild and glistening stare; and general emaciation soon manifests itself. The body then exhales a peculiar fœtor, and the skin is covered with a brownish, dirty-looking, and offensive secretion. The bodily strength rapidly declines; the sufferer totters in walking, his voice becomes weak, and he is incapable of the least exertion. The mental powers exhibit a similar prostration; at first there is usually a state of stupidity, which gradually increases to imbecility, so that it is difficult to induce the sufferer to make any effort for his own benefit; and on this a state of maniacal delirium frequently supervenes. Life terminates either in the mode described in Chossat's observations, or, as occasionally happens, in a convulsive paroxysm.*—On post-mortem examination, the condition of the body is found to be such as the results of Chossat's observations would indicate—namely, extreme general emaciation and disappearance of fat,† diminution in the bulk of the principal viscera, and almost complete bloodlessness, save in the brain, which still receives its usual supply. It is especially worthy of note that the coats of the small intestines are peculiarly thinned, so that they become almost transparent; and that the gall-bladder is almost invariably turgid with bile, the cadaveric exudation of which tinges the surrounding parts And further, the body rapidly passes into decomposition.

82. Now it is peculiarly worthy of note that the deficient supply of new histogenetic materials appears to check the elimination and removal of those which have become effete; for in no other way can we account for that tendency to putrescence, which is so remarkably manifested during life in the fœtid exhalation and in the peculiar secretion from the skin, and which is shown after death in the rapidity with which putrefaction supervenes. Moreover, towards the close of many exhausting diseases, the fatal termination of which is really due to a chronic inanition, it frequently happens that a "colliquative diarrhœa" comes on, which must be considered as a manifestation of the general disintegration that is making progress even during life. Now, referring to the conditions hereafter to be enumerated, as those which favour the operation of zymotic poisons in the body, it is obvious that no state could be more liable to it than this; since we have not merely that general depres-

* See Rostan in "Diction. de Médecine," art. 'Abstinence;' and Dr. Donovan's 'Account of the Irish Famine of 1847' in the "Dublin Medical Press," Feb. 1848; also a paper by Martin, "Med. T. and Gaz." April, 1861.

† In cases of *acute* starvation, as Dr. Fowler has shown in reference to the case of the Welsh fasting girl (*Lancet*, vol. ii. 1870, p. 150), a considerable amount of fat may be present in the body, and emaciation may not be marked.

sion of the vital powers, which is a predisposing cause of almost any kind of malady, and pre-eminently so of zymotic diseases, but also the presence of a large amount of disintegrating matter in the blood and general system, which forms the most favourable nidus possible for the reception and multiplication of such poisons. And thus it happens that pestilential diseases must certainly follow in the wake of a famine, and carry off a far greater number than perish from actual starvation.

83. Another class of phenomena, however, results from such a deficiency of alimentation as is not adequate to produce the results just described; provided this deficiency be prolonged for a considerable length of time, and especially if it be conjoined with other unfavourable conditions. Of this, a remarkable example was presented at the Millbank Penitentiary in 1823. The prisoners confined in this establishment, who had previously received an allowance of from 31 to 33 oz. of dry nutriment daily, had this allowance suddenly reduced to 21 oz., animal food being almost entirely excluded from the diet scale. They were at the same time subjected to a low grade of temperature, and to considerable exertion; and were confined within the walls of a prison situated in the midst of a marsh which is below the level of the adjoining river. The prison had been previously considered healthy; but in the course of a few months, the health of a large proportion of the inmates began to give way. The first symptoms were loss of colour, and diminution of flesh and strength; subsequently diarrhœa, dysentery, and scurvy; and lastly adynamic fevers, or headache, vertigo, convulsions, maniacal delirium, apoplexy, &c. The smallest loss of blood produced syncope, which was frequently fatal; and after death, ulceration of the mucous lining of the alimentary canal was very commonly found. Out of 860 prisoners, no fewer than 437, or 52 per cent., were thus affected. The influence of concurrent conditions, especially of previous confinement, was here remarkably shown; for those were found to be most liable to disease who had been in prison the longest. That the reduction of the allowance of food, however, was the main source of the epidemic, was proved by the two following facts:—The prisoners employed in the kitchen, who had 8 oz. of bread additional per day, were not attacked, except three who had only been there a few days; and after the epidemic had spread to a great extent, it was found that the addition of 8 oz. to the daily allowance of vegetable food, and $\frac{1}{2}$ oz. to the animal, greatly facilitated the operation of the remedies which were used for the restoration of health.* Very similar observations to these were made by Dr. Jones† on the prisoners confined in Camp Sumpter, one of the Southern prisons, during the late American civil war.‡

* See Dr. Latham "On the Diseases in the Millbank Penitentiary, 1824." A similar example of the effects of prolonged insufficiency of diet was furnished at the Maison Centrale of Nimes, for a highly instructive account of which by M. Boileau-Castelnau, chief physician to the 'Maison Centrale,' see "Ann. d'Hygiène Publ." Janv. 1849.

† See Dr. Austin Flint's "Physiology of Man," vol. ii. p. 39, 1867.

‡ The prisoners numbered upwards of 30,000, and were confined in a space of 27 acres, with little or no shelter from the intense heat of a Southern sun, or from the rain and dew, with festering masses of filth at the very doors of their rude dens and huts, and with the greater portion of the banks of the stream flowing through the stockade, a filthy quagmire of human excrements alive with maggots. The diet consisted of only $\frac{1}{3}$ lb. bacon and $1\frac{1}{4}$ lb. of meal, and even this was sometimes reduced. As a consequence of exposure to these conditions, in less than seven months 10,000 Federal prisoners died, the chief causes of this frightful mortality being diarrhœa, dysentery, scurvy, and hospital gangrene, the last often supervening on the slightest scratch of the surface, or even on the bites of small insects. It is curious to notice that contagious fevers were rare, and typhus unknown. Dr. Jones remarks, in full confirmation of Chossat's experiments on birds, that whilst large numbers of the Federal prisoners were utterly disgusted with the Indian corn supplied to them, in which, for the most part, the husk was not separated from the meal, yet that an urgent feeling of

The diminished power of resisting deleterious influences produced by insufficient aliment was well shown on a large scale by the statistics collected by Dr. Chenu, of the relative mortality of the French and English contingents in the Crimean war. During the first winter (1855) the English army lost 5·79 per cent. of its effective force, whilst the French only lost 2·31 per cent. Great changes were immediately introduced into the diet and general regimen of the English army, with the result that in the following winter, only 441 soldiers succumbed to disease, out of an effective of 50,000, whilst the French troops, badly fed and badly clothed, had no less than 106,000 sick, of whom 20,000 died, out of a total force of 130,000 men. The effects of insufficient alimentation were also exhibited on a large scale during the siege of Paris. The mortality among the feebler members of the community—old people and children—being very great. Besides the soldiers killed in action, upwards of 42,000 persons died in the course of the five months of siege, in excess of the number dying in the corresponding period of the preceding year.* The proportion steadily rose week by week as the supply of food decreased with only one or two exceptions, from the number 1272, who died in the week ending 24th September, 1870, to the number of 4671, who died in the week ending the 3rd February, 1871, the numbers in the three subsequent weeks being rather less.†

84. It is a curious effect of insufficient nutriment, as shown by the inquiries of Chossat (Op. cit.), that it produces an incapability of digesting even the small amount consumed. He found that when turtle-doves were supplied with limited quantities of corn, but with water at discretion, the whole amount of food taken was scarcely ever actually digested; a part of it being rejected by vomiting, or passing off by diarrhœa, or accumulating in the crop. It seems as if the vital powers were not sufficient to furnish the requisite supply of gastric fluid, when the body began to be enfeebled by insufficient nutrition; or perhaps we might well say, the materials of the gastric fluid are wanting. Hence the loathing of food, which is often manifested by those who have been subjected to the influence of an insufficient diet scale in our prisons and poor-houses, and which has been set down to caprice or obstinacy, and punished accordingly, may be actually a proof of the deficiency of the supply which we might expect to have been voraciously devoured, if really less than the wants of the system require.

85. It is extremely important that the Medical Practitioner should be aware that many of the phenomena above described may be induced by the adoption of a system of too rigid abstinence in the treatment of various diseases; and that they have been frequently confounded with the symptoms of the malady itself, and have led to an entirely erroneous method of treating it. "Many cases," says Dr. Copland,‡ "have occurred to me in practice, where the antiphlogistic regimen, which had been too rigidly pursued, was itself the cause of the very symptoms which it was employed to remove. Of these symptoms, the affection of the head and delirium are the most remarkable, and the most readily mistaken for an actual disease requiring abstinence for its removal." The experience of those, especially, who are largely engaged

hunger was not a prominent symptom, and that even when it existed at first, it soon disappeared, the muscular strength at the same time becoming rapidly diminished, the tissues wasted, and the mental faculties to the last degree lethargic.

* Le Bon, "La Vie," &c., Paris, 1874, p. 71. From 18th Sept. 1869, to 24th Feb. 1870, 21,978 persons died; whilst from 18th Sept. 1870, to 24th Feb. 1871 (period of siege), the number of deaths was 64,154.

† See M. Le Bon, "La Vie," &c , 1874.

‡ "Dictionary of Practical Medicine," vol. i. p. 26.

in consulting practice, must have furnished numerous illustrations of the above statement. Dr. Copland mentions the following:—"A professional man had been seized with fever, for which a too rigid abstinence was enforced, not only during its continuance, but also during convalescence. Delirium had been present at the height of the fever, and recurred when the patient was convalescent. A physician of eminence in maniacal cases was called to him, and recommended that he should be removed to a private asylum. Before this was carried into effect, I was requested to see him. A different treatment and regimen, with a gradual increase of nourishment, were adopted, and he was well in a few days, and within a fortnight returned to his professional avocations."

86. The time during which life can be supported under entire abstinence from food or drink, is usually stated to vary from eight to ten days;* the period may be somewhat prolonged, however, by the occasional use of water, and still more by a very small supply of food; or even, it would seem, by a moist condition of the surrounding atmosphere, which obstructs the exhalation of liquid from the body. Thus, Foderé mentions that some workmen were extricated alive after fourteen days' confinement in a cold damp vault, in which they had been buried under a ruin. Dr. Sloan has given an account† of the case of a healthy man, æt. 65, who was found alive after having been shut up in a coal-mine for twenty-three days, during the first ten of which he was able to procure and swallow a small quantity of foul water; he was in a state of extreme exhaustion, and died three days afterwards, notwithstanding the attempts made to recover him. It would seem as if certain conditions of the nervous system, especially those attended with peculiar emotional excitement, are favourable to the prolongation of life under such circumstances. Thus, in a case recorded by Dr. Willan, of a young gentleman who starved himself under the influence of a religious delusion, life was prolonged for sixty days; during the whole of which time, nothing else was taken than a little orange-juice. In a somewhat similar case which occurred under the Author's notice, in the person of a young French lady, more than fifteen days elapsed between the time that she ceased to eat regularly, and the time of her being compelled to receive nourishment; during this period she took a good deal of exercise, and her strength seemed to suffer but little, although she swallowed solid food only once, and then in small quantity. Again, in certain states of the system commonly known as "hysterical," there is frequently a very remarkable disposition for abstinence, and power of sustaining it. It may be well to remark that, under such circumstances, the continual persuasions of anxious friends are very injurious to the patient, whose return to her usual state will probably take place the earlier, the more completely she is left to herself.

3. *Movements of the Alimentary Canal.*

87. The motions by which Food is conveyed to the *Mouth* and introduced into its cavity, constituting the acts of *Prehension* and *Ingestion*, are ordinarily considered to be *voluntary*, at least in the adult; and it is indubitable that the Will has entire control over them. Nevertheless, they belong to the class

* There seems adequate evidence that a state which may be characterized as one of *Syncope*—the animal functions being entirely suspended, and the organic functions being reduced to an extremely low ebb—may be prolonged for many days, or even weeks, provided the temperature of the body be not too much reduced. This class of facts, however, will be more appropriately considered hereafter (CHAP. XXI.).

† "Medical Gazette," vol. xvii. p. 389. F. The Welsh Miners, *Lancet*, Ap. 28, 1877, were 9 days without food, except a few candles, and recovered.

of "secondarily automatic" movements; and like those of locomotion, may be kept-up when the will is in abeyance, by the suggesting and guiding influence of sensations, thus being performed under the same essential conditions as the purely "consensual" or "sensori-motor" actions.* The necessity of "guiding sensations" for their performance is made evident by one of Sir C. Bell's experiments, the wrong interpretation of whose results originally led him to an erroneous view of the functions of the Fifth pair of nerves. He found that an Ass, in which the infra-orbital branch of this nerve had been divided, made no attempt to pick up oats with its lip, although the animal saw them, bent-down its head with the obvious purpose of ingesting them, and brought its lip into absolute contact with them; hence he concluded that the power of *motion* was destroyed in the lip, when it was in reality only the *guiding sensation* that was deficient, the motor power being supplied by the Facial nerve or Portio dura.

88. The food thus introduced into the mouth is subjected (unless it be already in a state which needs no further reduction) to the process of *Mastication*. This is evidently an operation of great importance, in preparing the substances to be afterwards operated-on for the action of their solvent; and it exactly corresponds with the trituration to which the Chemist would submit any solid matter, that he might present it in the most advantageous form to a digestive menstruum. The complete disintegration of the alimentary matter is, therefore, of great consequence; and, if imperfectly effected, the subsequent processes are liable to derangement. Such derangement we continually meet with; for there is not, perhaps, a more frequent source of Dyspepsia than imperfect mastication, whether resulting from the haste with which food is swallowed, or from the want of the instruments proper for the reducing operation. The mechanical disintegration of the food is manifestly aided by Insalivation; but the admixture of Saliva also exerts, as we shall hereafter see, a very marked influence on the chemical composition of certain of its constituents. The movements of Mastication, still more than those already adverted-to, although under the complete control of the Will, and originally dependent upon it for their excitation, come at last to be of so *habitual* a character, that they continue when the direct influence of the will is withdrawn, the influence of the guiding "sensation," however, being essential to their performance. Every one is conscious that the act of mastication may be performed as well, when the mind is attentively dwelling on some other object, as when directed to *it;* but, in the former case, we are rather apt to go on chewing and rechewing what is already fit to be swallowed, simply because the will does not exert itself to check the action, and to carry the food backwards within the reach of the muscles of deglutition. This conveyance of food backwards to the fauces is a distinctly voluntary act; and it is necessary that it should be guided by the sensation which there results from the contact it induces. If the surface of the pharynx were as destitute of sensation as is the lower part of the œsophagus, we should not know when we had done what was necessary to excite its muscles to operation.—The muscles depressing the lower jaw are the genio-hyoid, the mylohyoid, and the anterior belly of the digastric. The omo-hyoid, sterno-hyoid, and thyro-hyoid muscles, also aid. The upward

* This, the Author thinks, will be conformable to the experience of most of his readers; who will find, if they analyze their own consciousness, that they continue to eat while their whole *attention* is given to some abstract train of thought, or to some external object. But a remarkable case has been placed on record by Mr. Dunn (*Lancet*, Nov. 15 and 29, 1845), which fully confirms the view here advanced; the movements, not merely of the lips and jaws, but those by which food was conveyed to the mouth, having been carried on *automatically*, when once (so to speak) the spring was touched by which they were set in action.

movement is effected by the combined action of the masseter, temporal and internal pterygoid muscles. The forward movement is due to the action of both pterygoids, and the lateral or grinding movement to the external pterygoid of one side. The Tongue is moved downwards and forwards by the hyo-glossus and genio-glossus, upwards and backwards by the stylo-glossus, whilst its changes of form are due in great measure to its intrinsic longitudinal and transverse fibres. The more important muscles concerned in the mastication of food are supplied by the third branch of the Fifth pair, which is well known to be a nerve of mixed endowments; but some, especially those of the cheeks, are also supplied by the Facial nerve; and yet, if the former be paralyzed, the latter cannot stimulate them to the necessary combined actions. Hence we see that the movements are of an associated character, their due performance being dependent on the part of the nervous centres, from which the motor influence originates. If the Fifth pair, on the other hand, be uninjured, whilst the Portio dura is paralyzed, the movements of mastication are performed without difficulty; whilst those connected in any way with the Respiratory function, or with Expression, are paralyzed. If, again, the sensory portion of the Fifth pair be paralyzed, the act of Mastication is very imperfectly performed, even though the motor power be not in the least impaired; for the muscles cannot be made to perform the requisite associated movements without the guidance of sensations; so that the morsel lodges between the teeth and the cheek, or beneath the tongue, and can with difficulty be kept in the appropriate position.

89. When the reduction of the food in the mouth has been sufficiently accomplished, it is carried into the *Pharynx*, and is thence propelled down the œsophagus into the stomach, by a set of associated movements, which, taken together, constitute the act of *Deglutition*.* The *first* stage in the process is purely voluntary, and consists in the carrying back of the food until it has passed the anterior palatine arch; this is effected by the contraction of the mylo-hyoid, and of the longitudinal and transverse muscles of the tongue, which together render the tongue shorter and thicker, pressing it against the roof of the mouth, whilst the stylo-glossi draw it somewhat backward. The *second* stage now commences, during which the entrance of food into the nasal cavities and trachea is most jealously guarded against by certain reflex actions, which have only been clearly recognized since the introduction of the laryngoscope by Czermak. During this stage the tongue is carried still farther backwards, the larynx rises, its orifice being covered by the epiglottis, which is at the same time somewhat depressed, and placed horizontally, so that its upper border touches the posterior wall of the pharynx.† The cushion at the base of the epiglottis becomes applied to the arytenoid cartilages, and the vocal cords, both true and false, are closely approximated; a triple protection against the entrance of the food into the trachea being thus afforded. Coincidently with these movements, the lower border of the velum palati becomes applied to the walls of the pharynx, and the muscles of the posterior palatine arch contract in such a manner, as to cause the sides of the arch to approach each

* These movements were first described in detail by Magendie; but his account requires some modification, through more recent observations. See those of Dzondi, in Prof. Müller's "Elements of Physiology" (translated by Dr. Baly), p. 501; Budge ("Phys.," 1860, p. 157); Bidder ("Neue Beobachtungen," Dorpat, 1838); Czermak "The Laryngoscope," New Syd. Soc. Translation, 1861, vol. xi.; Schuh "On the Laryngoscope," Canstatt, 1858; and Moura Robin's "Journal de l'Anatomie," 1867, p. 157; Chauveau in Brown-Séquard's "Journal de la Physiologie," 1862, p. 211; A. Mosso, "Centralblatt der Med. Wiss.," 1874, p. 263).

† The presence of the epiglottis is not essential. After its ablation cats and dogs can still swallow without difficulty or the entrance of food into the larynx. See Walton in Foster's "Journ. of Physiology," vol. i. 1878, p 303.

other like a pair of curtains, the passage from the fauces into the posterior nares being nearly closed by them; and to the cleft between the approximated sides the uvula is applied like a valve. A sort of inclined plane, directed obliquely downwards and backwards, is thus formed; and the morsel slides along it into the pharynx, which is brought-up to receive it, by the action of the stylo- and palato-pharyngei muscles. Though some of these acts may be performed voluntarily, the combination of the whole is automatic.* The *third* stage of the process, the propulsion of the food down the œsophagus, then commences. This is accomplished, in the upper part, by means of the constrictors of the pharynx; and in the lower, by the muscular coat of the œsophagus itself, which is composed in its upper part of striated muscular tissue alone, in its middle part of exclusively unstriated muscular tissue, and near the cardiac orifice of the stomach of a mixture of striated and unstriated tissue.† When the morsels are small, and are mixed with much fluid, the undulating movements from-above-downwards succeed each other very rapidly, as may be well observed in Horses whilst drinking; large morsels, however, are frequently some time in making their way down. Each portion of food and drink is included in the contractile walls, which are closely applied to it during the whole of its transit. The gurgling sound which is observed when drink is poured down the throat of a person in *articulo mortis*, is due to the want of this contraction. The whole of the third stage is completely involuntary.—In order to ascertain the parts implicated in the deglutition of liquids, Dr. Moura employed the laryngoscope after ink had been swallowed, and found that the parts tinted were the whole internal surface of the mouth, the velum palati, uvula, pillars of the fauces, anterior surfaces of the epiglottis and the pharynx generally, with the posterior surfaces of the cricoid and arytenoid cartilages. On the contrary, the parts that preserved their natural colour were the interior of the larynx to within a very short distance of the free edge of the epiglottis and the anterior portion of the lateral grooves of the fauces. At the point where the œsophagus enters the stomach, the "cardiac orifice" of the latter, there is a sort of sphincter, which is usually closed, but which opens when sufficient pressure is made on it by accumulated food, closing again, when this has passed, so as to retain it in the stomach.‡

90. The purely *automatic* nature of the act of Deglutition is shown by the fact, that no attempt on our part will succeed in performing it really *voluntarily*. In order to excite it, we must apply some stimulus to the fauces. A very small particle of solid matter, or a little fluid (saliva, for instance), or the contact of the back of the tongue itself, will be sufficient; but without either of these, *we cannot swallow at will*. Nor can we restrain the tendency, when it is thus excited by a stimulus; every one knows how irresistible it is, when the fauces are touched in any unusual manner; and it is equally beyond the

* The observations of Schuh (Canstatt, 1858) upon the movements of the soft palate during deglutition seem to show that this part is somewhat more active during the second stage than it was described to be by Dzondi. He had an opportunity of observing them in a woman, the left side of whose face had been removed by an operation. When the patient drank, the soft palate raised itself above the horizontal line, as soon as the glass was approximated to her lips. It remained in this position whilst the fluid was being sucked in; but as soon as swallowing commenced it very suddenly descended, so as to press the fluid into the œsophagus. It then again elevated itself with even greater tension, and again descended. In swallowing solid food the same sudden ascent and descent of the velum upon the deglutition of each morsel was observable. See also Brücke's "Vorlesungen," Band i. 281.

† Gillette, "Journ. de l'Anatomie," 1872, p. 617. See also for the Histology of the Alimentary Canal, Klein and Verson in Stricker's "Manual of Histology," Syd. Soc. Transl. vol. i.

‡ The closure of the sphincter has been disputed by Giannuzzi.

direct control of the will, in the ordinary process of eating,—voluntary as we commonly regard this. Moreover, this action is performed, like that of respiration, when the power of the will is suspended, as in profound sleep, or in apoplexy affecting only the brain; and it does not seem to be at all affected by the entire removal of the brain, in an animal that can sustain the shock of the operation; being readily excitable, on stimulating the fauces, so long as the nervous structure retains its functions. But if the "nervous" circle be destroyed, either by division of the trunks, or by injury of any kind to the portion of the nervous centres connected with them, the action can no longer be performed; and thus we see that, when the effects of apoplexy are extending themselves from the brain to the spinal cord, whilst the respiration becomes stertorous, the power of Deglutition is lost, and then respiration also speedily ceases.

91. The *nerves* specially concerned in this action are connected with a *reflex centre* situated in the lower part of the medulla oblongata, named the accessory olivary body, the mechanism of which is such that under normal conditions the motor impulses liberated affect first the muscular fibres of the upper part of the œsophagus, and then those of the lower. The centre cannot be excited from the œsophagus, the sensibility of which is low, since if a morsel of food be introduced into it from without, it remains stationary at the point where it has been inserted, until a swallowing movement commencing in the pharynx is propagated to it.* On the other hand, the motor impulse once liberated from the centre, spreads itself from above downwards through the whole length of the œsophagus, as is shown by the fact that if a piece of string be attached to a morsel of meat, and this is pulled up after having been allowed to descend half-way down the œsophagus, the wave of contraction is propagated to the stomach. Even the excision of a complete ring of the œsophagus does not arrest this propagation of the peristaltic contraction of the tube.† The *centripetal* or *sensory impressions* are conveyed to the medullary centre along the descending palatine branches of the second division of the Fifth pair distributed upon the fauces, and along the superior laryngeal branches of the pneumogastric distributed upon the pharynx. The *centrifugal* or *motor impulses* traverse the pharyngeal branches of the Pneumogastric, which are probably originally derived from the Spinal accessory; the branches of the Hypoglossal, distributed to the muscles of the tongue, and to the sterno-hyoid, sterno-thyroid, and thyro-hyoid muscles; the motor filaments of the Recurrent laryngeals; some of the branches of the Fifth, supplying the levator muscles of the lower jaw; the branches of the Facial, ramifying upon the levator palati mollis, the digastric and stylo-hyoid muscles, and upon those of the lower part of the face; and probably some of the branches of the Cervical plexus, which unite themselves to the descendens noni. It was further observed by Dr. Reid‡ that the stylo-pharyngeus muscle is usually thrown into contraction when the roots of the Glosso-pharyngeal nerve are irritated; and as this has been also noticed by Mayo, Volkmann, and others, we are probably to consider the Glosso-pharyngeal a motor nerve, in so far as that muscle is concerned.§ Swallowing

§ Op. cit. pp. 258—260. It seems not improbable that the discrepant results obtained by different experimenters on this point are partly to be explained by differences in the distribution of the nerves in the several species of animals operated on. Thus in the experiments of Prévost and Waller on the *Rabbit* (Brown-Séquard's "Archives de Physiologie,"

movements can be initiated by stimulation of the larynx, or by direct irritation of the superior laryngeal nerve, of the trunk of the vagus in the neck, or of the recurrent laryngeal nerve.

92. In the propulsion of the food through the œsophagus we have a distinct case of *reflex action, without sensation*, occurring as one of the *regular associated movements* in the natural condition of the animal body; and it is very interesting to find this following upon a reflex action *with* sensation (that of the pharynx), and preceding a movement which is but slightly connected with the Spinal Cord (that of the lower part of the alimentary canal). The use of sensation in the former case has been already shown. The muscular fibres of the Œsophagus are *also* excitable, though usually in a less degree, by *direct* stimulation; for it appears that, in some animals (the Dog, for example), section of the pneumogastric does not produce that check to the propulsion of the food which it occasions in the Rabbit; and even in the Rabbit, as Dr. M. Hall has remarked,* the simple contractility of the muscular fibre occasions a distinct peristaltic movement along the tube, after its nerves have been divided; causing it to discharge its contents when cut across. Such a movement, indeed, seems to take place in something of a rhythmical manner (that is, at short and tolerably regular intervals), whilst a meal is being swallowed; but as the stomach becomes full, the intervals are longer, and the wave-like contractions less frequent. The re-opening of the cardiac orifice, on pressure from *within* (which is usually resisted by the sphincter, as in the acts of defæcation, parturition, &c.), is one of the first of that series of reversed actions which constitutes the act of *Vomiting;* and this is accompanied by a reversed peristaltic action of the œsophagus. The independence of these actions, one of another, and their relation to a common cause, is remarkably shown by the fact, that when vomiting takes place as a consequence of the injection of tartar-emetic into the veins, the reversed peristaltic action of the œsophagus is performed even after its separation from the stomach.

93. The food which, thus propelled along the œsophagus, enters the *Stomach* through its cardiac orifice in successive waves, is immediately subjected to a peculiar peristaltic movement, which has for its object to produce the thorough intermixture of the gastric fluid with the alimentary mass, and so to separate the portion which has been sufficiently reduced, from the remainder. The fasciculi composing the muscular wall of the Human stomach have been shown by Dr. J. B. Pettigrew† to be so disposed as to form long spirals or figure-of-eight loops, of which the most external and most internal fibres are nearly longitudinal, whilst those most centrally situated are nearly circular. The contraction of these fibres lessens the diameter of the stomach in every direction; and whilst the cavity is empty, they are uniformly

1870, pp. 185 and 343), it appeared that in this animal the glosso-pharyngeal nerve takes no part in the reflex phenomena of deglutition, the fifth being the principal sensory nerve, and the superior laryngeal branch of the pneumogastric contributing to the reflex movement by its sensory branches distributed to the mucous membrane covering the epiglossus, the arytenoepiglottidean folds, the superior borders of the laryngeal orifice and the cartilages of Santorini. In Chauveau's experiments on the *Horse* ("Journal de la Physiologie," t. v. pp. 190 and 323), direct irritation of the upper roots of the vagus caused contraction chiefly of the inferior constrictor and of the œsophagus; of the middle roots, contraction of the pharynx generally; and of the lower roots, contraction of the upper constrictor and levator; though all acted to some extent upon the whole pharynx and œsophagus. The spinal accessory, glosso-pharyngeal, facial, hypoglossal, and cervical sympathetic nerves, had little or no action on the movements of the pharynx, œsophagus, or stomach in this animal. See also Goltz ('Studien,' &c., in Pflüger's "Archiv," 1872, vi. p. 616), for the movements of the œsophagus in the *Frog*.

* "Third Memoir on the Nervous System," § 201.

† "Proceed. of the Roy. Soc. Lond.," June 20, 1867.

contracted, so as to reduce the organ to its smallest dimensions. When food is introduced the stomach rotates on its long axis, the surface that looks forwards in the fasting state becoming more and more superior; the contraction of the parietes as a whole still continues to such a degree as to make them closely apply themselves to its surface; but the contraction of the individual fasciculi alternates with relaxation in such a manner as to induce a great variety of motions in this organ, sometimes transversely, and at other times longitudinally. "These motions," remarks Dr. Beaumont, who has enjoyed a peculiar opportunity of observing them,* "not only produce a constant disturbance or *churning* of the contents of the stomach, but they compel them at the same time to revolve about the interior from point to point and from one extremity to the other." In addition to these movements, there is a constant agitation of the stomach, produced by the respiratory muscles. The nature of these, and indeed of all peristaltic movements, has been stated by Dr. Brinton† to resemble very closely those produced by the descent of a perforated piston in a closed tube containing fluid, for here there would be peripheral currents passing in the same direction as the piston, and a central current flowing in the opposite direction, through the perforation in the piston. The direction which the particles of food take, as described by Dr. Beaumont, corresponds very fairly with this view. He says:—"The bolus as it enters the cardia, turns to the left, passes the aperture, descends into the splenic extremity, and follows the great curvature towards the pyloric end. It then returns, in the course of the smaller curvature (or as Dr. Brinton supposes, through the axis of the stomach), and makes its appearance again at the aperture in its descent into the great curvature, to perform similar revolutions. These revolutions are completed in from one to three minutes. They are probably induced, in a great measure, by the circular or tranverse muscles of the stomach. They are slower at first, than after chymification has considerably advanced;" at which time also there is an increased impulse towards the pylorus. It is probable that, from the very commencement of chymification, until the organ becomes empty, portions of chyme are continually passing into the duodenum; for the bulk of the alimentary mass progressively diminishes, and this the more rapidly as the process is nearer its completion. The accelerated expulsion appears to be effected by a peculiar action of the transverse muscles; and especially of that portion of them which surrounds the stomach at about four inches from its pyloric extremity. This band is so forcibly contracted at the latter part of the digestive process that it almost separates the two portions of the stomach into a sort of hour-glass form; and Dr. Beaumont states that, when he attempted to introduce a long thermometer-tube into the pyloric portion of the stomach, the bulb was at first gently resisted, then allowed to pass, and then grasped by the muscular parietes beyond, so as to be drawn-in: whence it appears that the contraction has for its object, to resist the passage of solid bodies into the pyloric extremity of the stomach, at this stage of digestion, whilst the matter which has been reduced to the fluid form is pumped-away (as it were) by the action of that portion of the viscus. These peculiar motion continues until the stomach is perfectly empty, and not a particle of

* See the "Case of Alexis St. Martin, with Observations and Experiments by Dr. Beaumont," republished in this country by Dr. Andrew Combe.—This patient had a large fistulous orifice in his stomach, remaining after a wound which had laid-open the cavity; but his general health had been completely restored.

† "Cyclop. Anat. and Phys." vol. v. pp. 313 and 345. See also, supporting Dr. Brinton's views, the observations of Dr. v. Braam Houckgeest (Pflüger's "Archiv," 1872, Band vi. p. 300). In these experiments the belly of the animal was opened whilst the animal was immersed in a solution, containing 6-10ths per cent. of common salt in water, at blood heat.

food or of chyme remains: and when they are nearly brought to a close, the contraction of the pyloric orifice also gives way to an extent sufficient to allow not only the undigested residue of the food, but also large solid bodies that may have been swallowed (such as coins and the like), to pass into the intestinal canal.

94. With regard to the degree in which these movements of the Stomach, whose share in the Digestive operation is so important, are dependent upon the Spinal cord, and are consequently of a "reflex" nature, it is difficult to speak with certainty, owing to the contradictory results obtained by different experimenters. These contradictions, however, seem partly due to a diversity in the nature of the animals experimented-on, and partly to a difference in the stage of the digestive process at which the observations were made. The *nerves* supplying the Stomach are derived from the Pneumogastrics, and from branches of the solar plexus of the Sympathetic, and it seems to be well established by the researches of Reid, Valentin, and others,* that distinct movements commencing at the cardiac orifice, and extending peristaltically towards the pylorus may be excited, when the Stomach is distended with food, by irritating the Pneumogastric. The movements, however, are comparatively feeble when the Stomach is empty. When the Pneumogastrics are divided in the neck, the cardiac orifice of the stomach becomes spasmodically contracted† —a condition which, after lasting for about thirty-six hours, generally passes off. If previously to that period the animal be allowed to eat, the food accumulates in the lower part of the œsophagus, and death results from suffocation. The contraction of the cardiac sphincter appears, therefore, to be induced by other nerves than the Pneumogastric; but there is abundant evidence to show that all the ordinary movements of the stomach are governed by the Pneumogastrics (or, perhaps, as Schiff believes, by the fibres of the Spinal Accessory coursing in the Pneumogastrics), since, if these be divided, complete paralysis of the muscular walls results, whilst lively movements can still be induced by irritation of the lower or distal cut extremity. Irritation of the splanchnic nerves, or of the sympathetic cord, is not followed by any very obvious movements, the former nerves being in fact essentially vaso-motor, and as when stimulated they cause contraction of the blood-vessels, they rather tend to inhibit any movements that may be present, than to incite them if they are absent. It is found that after the section of the Pneumogastrics, if small portions of food be introduced into the stomach, these can be still propelled onwards, which we must consider to be due either, as Ludwig‡ and Schiff§ suppose, to the reflex action of the ganglia of the Sympathetic, which are very numerous in the connective tissue layers of its parietes, or possibly to the contractions of the muscular fibres produced by direct irritation, a view which originally advanced by the Author has been strongly advocated by Engelmann.‖ The moderate excitement of pleasurable emotions is favourable to the operation of digestion; not only by

giving firmness and regularity to the action of the heart, and thus promoting the circulation of the blood and the increase of gastric secretion, but also in all probability by imparting energy and regularity to the muscular contractions of the stomach. The movements of the stomach cease during sleep.*

95. Much discussion has taken place upon the question, how far contraction of the parietes of the Stomach itself actually participates in the operation of *Vomiting;* and many experiments have been made to determine the facts of the case. Some, like Magendie, have gone so far as to affirm that the stomach is essentially passive; grounding this inference upon the fact experimentally ascertained, that when the stomach was removed, and a bladder was substituted for it, this was emptied of its contents by the compression of the parietes of the abdomen, when tartar-emetic was injected into the veins.† But this fact by no means disproves the active co-operation of the stomach; and judging from the analogy of the uterus, bladder, and rectum,—whose muscular walls are all actively concerned in the expulsion of their contents, though that expulsion is in great part due to the contraction of the abdominal muscles,—we should be led to concur with the common opinion, of which our own sensations during the act would indicate the correctness. From the careful experiments of Schiff‡ on dogs, as well as from observations made on man in cases where, from injury, the stomach has been exposed,§ it appears that under ordinary circumstances the cardiac aperture is firmly closed; but that when vomiting is about to take place, a full inspiration occurs, which serves, as Dr. M. Hall first pointed out, to fix the diaphragm and to supply a firm surface against which the stomach can be pressed. Then, an instant before the contraction of the abdominal walls occurs, the cardiac orifice is suddenly dilated by the contraction of special bands of muscular fibres, which are probably continuous with the longitudinal fibres of the œsophagus. The muscles of expiration—*i.e.*, the abdominal muscles—then contract with great vigour, and the glottis being closed, so that the escape of air from the chest and the elevation of the diaphragm are prevented, the stomach is subjected to considerable pressure, and its contents are immediately ejected. The importance of the contraction of the abdominal muscles is sufficiently evidenced by the fact, demonstrated by Giannuzzi, that no vomiting can be induced in animals whose voluntary muscles have been paralyzed by curare. When peristaltic movements of the stomach, which have occasionally been observed to be reversed in direction, are already present, their activity is generally intensified; but if the stomach be quiescent before vomiting commences, it may remain perfectly passive throughout. The pylorus is almost always firmly closed, so that but little of the food escapes into the intestine. The flow of bile is usually increased. The interesting observation was made by Rühle, that if a manometer be fastened into the stomach, and vomiting be excited, instead of an elevation there is a descent of the mercury, momentarily preceding the expulsion of the contents: this must doubtless be referred to the sudden and *active* opening of the cardiac orifice produced by the dilatator fibres described by Schiff, which occurs just antecedently to the pressure exerted by the muscles of the abdomen. There can be but little doubt that the violent but fruitless efforts at vomiting which we occasionally witness (two or three such

* Busch, Virchow's "Archiv," Band xiv. p. 166.

† Schiff has pointed out that for Magendie's experiment to succeed the cardiac orifice and lower part of the œsophagus must also be removed, the contraction of these parts otherwise preventing the escape of the contents of the bladder.

‡ Moleschott's "Unters.," Band x. 1867, p. 353.

§ Lepine, "Bullet. de l'Acad. Roy. de Méd.," 1844; and Patry, in "Allgem. Med. Centralblatt," 1863, No. 62.

efforts frequently preceding the effectual one), are prevented from emptying the stomach by the obstinacy with which the cardiac sphincter is kept closed; just as the expiratory effort which assists in emptying the stomach is prevented by the firmness with which the glottis is held shut, from expelling the contents from the chest. The immediate causes of vomiting may be reduced to several different categories. 1st. The contact of irritating substances with the mucous membane of the stomach itself; these, however, cannot act by *direct* stimulation upon more than its own muscular coat; and their operation upon the associated muscles must take place by *reflexion*, through the "nervous circle" furnished by the pneumogastrics and the motor nerves of expiration. 2nd. Irritations applied to other parts of the body, likewise operating by *simply-reflex* transmission; as in the vomiting which is consequent upon the strangulation of a hernia, or the passage of a renal calculus. 3rd. To the direct irritation of the nervous centres by certain irritants (Tartar Emetic, Apomorphin); and, perhaps we may add, the vomiting that occurs after division of *both* pneumogastrics—the division of one having but little effect.* 4th. Impressions received through the *sensorial* centres, which may be either sensational or emotional, but which do not operate unless they are *felt*. In this mode seems to be excited the vomiting that is induced by tickling the fauces, which first gives rise to the sensation of nausea; as well as the vomiting consequent upon disgusting sights, odours, or tastes, and upon those peculiar internal sensations which are preliminary to "sea-sickness." The *recollection* of these sensations, conjoined with the emotional state which they originally excited, may itself become an efficient cause of the action, at least in individuals of peculiarly irritable stomachs or of highly sensitive nervous systems; for this plays downwards upon the sensorial centres, in such a manner as to excite in them the same condition as that which was originally produced through the medium of the sensory nerve when the object was actually present. (See CHAP. XIII., Sect. 3.)

96. The passage of the Chyme, or product of the gastric digestion, through the pyloric orifice, into the commencement of the *Intestinal tube*, is at first slow; but when the digestive process is nearly completed, it is transmitted in

* This appears to be demonstrated by the experiments of Chouppe (Société de Biologie, Séance, 18 July, 1874), who observed that after section of both pneumogastrics in dogs, the intravenous injection of tartar-emetic and of apomorphin caused free vomiting, whilst Ipecacuanha or its active principle, Emetin, had no action; from whence the conclusion may be drawn that the two first-named drugs act on the vagal centre as well as upon the peripheric extremities of the vagi in the gastric mucous membrane, whilst the action of emetin seems to be confined to the latter. Hermann (Pflüger's "Archiv," Band v. 1872, p. 280) grounding his opinion on the result of an experiment made by Grimm (Idem, Band iv. 1871, p. 205), showing that tartar-emetic injected into the veins takes a longer time to act than when injected into the stomach, believes that this salt has a specific action on the parietes of the stomach; but it may be remarked that, as above stated, Magendie long ago showed that efforts to vomit followed the injection of tartar-emetic, after the ablation of the entire stomach. (See D'Ornellas' "Bulletin générale de Thérapeutique," 1873, p. 193 *et seq.*) D'Ornellas considers that vomiting may be produced by three kinds of efforts: 1, Intrinsic, or by the contraction of the stomach alone; 2, Extrinsic, or by the contraction of the expiratory muscles; and 3, by mixed or combined and co-ordinated, intrinsic and extrinsic efforts; and the nerves implicated may be either the pneumogastrics, the nerves of special sense, or the sympathetic. In meningitis, in cases of cerebral tumour, and in hæmorrhage, the feeling of nausea is probably conveyed by the sensory branches of the glosso-pharyngeal nerve. The nauseating principle of some drugs, though generally, is not always identical with that producing their emetic effect. Thus in the case of Ipecacuanha the nauseating principle is an odorous substance, capable of separation by ether, in which it is soluble, whilst the emetic principle is soluble in alcohol. The former can produce vomiting immediately on being swallowed, or even before by its action on the olfactory and glosso-pharyngeal nerves, whilst the latter acts as above stated on the vagal branches distributed to the stomach.

much larger quantities. The pyloric orifice, like the cardiac, is furnished with a sphincter muscle; but how far its contractions are dependent upon "reflex action" has not yet been ascertained. The ingested matter, which undergoes further changes of a very important character within this portion of the canal, is gradually propelled onwards by the peristaltic contractions of its walls; and these are excited by the contact, either of the products of digestion, or of the secretions poured in by the various glands that discharge their products into the intestinal tube.* In its progress along the small intestines, the nutritious portion of the ingested matter is gradually taken up by the blood-vessels and absorbents; and the residue, combined with excrementitious matters separated from the blood, begins to assume the fæcal character. A further absorption takes place during the passage of the fæcal matter through the large intestines; and thus by the time it reaches the rectum, it has acquired a considerable degree of consistency.

97. The nervous supply of the intestines is derived essentially from the sympathetic system; though some fibres may be derived from the pneumogastrics. The sympathetic fibres proceeding from the cœliac, mesenteric, and other plexuses accompany the blood-vessels to the intestines, and form a chain of nerves and nervous ganglia, the *Plexus myentericus*, one portion of which has been shown by Auerbach to lie between, and to supply both the circular and longitudinal layers of muscular tissue of the *small* intestines, and to be situated on the outside of the longitudinal layer in the *large* intestine, whilst another portion, discovered by Meissner, lies in the submucous areolar tissue, and is probably destined for the supply of the *muscularis mucosæ*, or muscular layer of the mucous membrane.† It might at first sight appear to be easy to determine the precise influence of the nervous system upon the muscular walls of the intestines, but experience has shown that the investigation is amongst the most difficult in experimental physiology, various results having been obtained according to the animal experimented on; the nature of the stimulus applied; the precise part stimulated; the state of distension of the tube; the fulness or emptiness of the blood-vessels; the venous or arterial condition of the blood circulating through the tissues, and the temperature at which the experiments are conducted. The inquiry is further complicated by the fact that the splanchnic nerves, which are the vaso-motor nerves of the vessels supplying the abdominal viscera, appear also, under certain circumstances, to exert an inhibitory influence on the intestinal movements. It may be certainly stated that in the fœtus, and during sleep, perhaps in consequence of the large relative quantity of oxygen contained in the blood in each of these states, and also when empty, the intestines are quiescent (*aperistalsis*), or at most their movements are extremely slow and feeble; but as soon as food is propelled

* The Bile seems to have an important share in producing this effect; since, when the ductus choledochus is tied, constipation always occurs. M. Legros and Onimus (Robin's "Journal de l'Anat.," 1869, pp. 37 and 163) have shown by tracings taken from a caoutchouc ball introduced into the intestines, that the peristaltic contractions move more rapidly in the duodenum (sometimes traversing 8 inches in the minute) than in the cæcum (6 inches) of the dog.

† Auerbach, Canstatt's "Jahresbericht," 1862, p. 174; Manz, "Die Nerven und Ganglien des Saugethierdarms," 1859; Krause, "Studien des Phys. Instit. zu Breslau," 1863, p. 41. "Unters. ub. einig. Ursach. der peristalt. Beweg. des Darmcanals;" and Virchow's "Archiv," 1864, p. 467. According to Gerlach (abstract in Humphry and Turner's "Journ. of Anat." vol. viii. 1874, p. 173) the myenteric plexus of Auerbach contains highly vascular ganglia and fasciculi of fibres, forming primary and secondary networks. From the secondary plexuses fine fibres arise, each of which ends in a corpuscle that may give off one or two processes, ending between the muscular fibres. Klein ("Q. J. of Mic. Sci.," Oct 1873) describes in addition to the above, isolated ganglion-cells, between the circular and longitudinal muscular coats.

into them from the stomach, peristaltic contractions commence, which force the contents onwards, and may become violent (*dysperistalsis*). These movements are of a reflex nature, the circuit consisting of centripetal sensory nerve-fibres distributed to the mucous membrane, which convey the impression produced by the presence of food to the ganglia of the plexuses of Auerbach and Meissner, from whence an impulse is reflected to the muscular tissues of the intestine, as may be understood from an examination of the accompanying wood-cut (Fig. 63). Coincidently with the entrance of food into the intestines, the blood-vessels become turgid with blood, a condition that appears greatly to heighten the irritability of the nervo-muscular apparatus, for stimuli which provoke no response when the vessels are comparatively empty, will produce well-marked effects when they are full.* A large amount of evidence has been accumulated, showing that the peristaltic movements may be influenced by distant cerebro-spinal and sympathetic centres, but the precise channels through which their influence is transmitted are still undetermined. Schiff† and Budge,‡ in experiments on cats, observed movements of the intestines follow stimulation of the *corpora striata*, *pons Varolii*, *medulla oblongata*, and other parts of the *encephalon*; and the remarkable influence of certain emotions, as fear, in increasing peristalsis, as well as the history of many pathological cases, supports the view that the cerebro-spinal nervous system can act more or less directly upon the intestines. Good evidence that the fibres by which irritation of the more remote sympathetic ganglia act upon the intestines are contained in the spinal cord, is afforded by the following experiment of M. C. Bernard:—The spinal cord is divided below the medulla oblongata, to abolish the influence of the Will. The chest is then opened, and the inferior cervical ganglion stimulated. After a few seconds, active movements of the small intestines takes place. The cord connecting the inferior cervical with the first thoracic ganglion is now divided, and the lower extremity stimulated. The intestines remain quiescent. But if the upper extremity be stimulated, active intestinal movements again occur.§ The *Pneumogastrics* are

† "Lehrbuch der Physiologie," 1859. ‡ "Lehrbuch der Physiologie," 1862, p. 785.

§ Experiments made like those of Pincus, Budge, Adrian, and Lamansky, with a view of determining the functions of the cœliac and mesenteric plexuses by noticing the effects of their ablation can scarcely be of any service, since the operation required is accompanied by much hæmorrhage and is so severe as to cause death in a few hours. However, the chief phenomena observed have been congestion, and ecchymoses in the mucous membrane of the stomach and small intestine, with hypersecretion of mucus, liquid fæces, and more or less severe peritonitis. M. Moreau, "Comptes Rendus," 1868, p. 554, has shown that section of the nerves supplying a fold of intestine leads to effusion into it.

believed by many to be also a channel by which impulses proceeding from the cerebro-spinal centres are transmitted to the intestines, since electrical excitation of these nerves usually, though not always, produces contractions which commence in the stomach, and are most evident when the splanchnics have been divided,* and also at a short interval after death. It must be admitted, however, that the effects of stimulating the pneumogastrics are very inconstant.†

98. The *Splanchnic nerves* are now well known to be the chief *vaso-motor* nerves of the abdominal viscera, but it is difficult to say whether, when irritated, they act directly upon the muscular fibres or nervous ganglia of the intestines, or whether their influence is exerted indirectly by modifying the size of the vessels, and the quantity of blood supplied to these parts. According to some experimenters,‡ when irritated by the application of exceedingly feeble currents of electricity, the splanchnics act like ordinary *motor* nerves, and produce contraction of the muscular coats of the intestine. If, however, the current be of moderate strength, so far from causing contraction, these nerves are declared by Pflüger,§ to *restrain* or *inhibit* the peristaltic movements, and many excellent observers corroborate his statements. On the other hand, there seems to be little doubt that shortly after death irritation of the splanchnics will produce peristaltic movements. To explain these phenomena, Nasse has suggested that the splanchnics may contain both motor and inhibitory as well as vasomotor fibres, the former being more irritable than the latter—that is to say, responding to a feebler stimulus, and at the same time retaining their irritability for a longer period after death. Nasse, experimenting on rabbits, found that the inhibitory effect of irritating the splanchnics immediately after death, was limited to the small intestines; the movements of the stomach, colon, and rectum remaining unaffected. The arrest of movement took place so quickly after the application of the stimulus to the nerves as to lead him to the conclusion that it was a direct effect, and not secondary to contraction of the blood-vessels. Kölliker states that the inhibitory power of the splanchnics is abolished by curare; and Brunton‖ was unable to perceive it in several animals narcotized by chloral. The splanchnics also contain *sensory* fibres.

99. The movements of the intestines appear further to be powerfully affected by the quantity of blood supplied to them, as well as by its arterial or venous quality. Nasse observed lively movements, both when the vessels were rendered anæmic by pressure on the aorta, and when blood was injected at a high pressure. S. Mayer and v. Basch¶ remark that compression of the thoracic aorta usually, but not always, causes vigorous contraction both of the longitudinal and circular muscular fibres of the intestines, which they attribute to the excitation

* Houckgeest, Pflüger's "Archiv," 1873, Band vi. p. 266.

† Legros and Onimus (Robin's "Journal de l'Anat. et de la Physiologie," 1869, p. 196) state that the application of interrupted currents of electricity to the pneumogastrics produces relaxation and immobility of the intestines, whilst continuous currents exert but little action upon them. Sanders Ezn (Humphry and Turner's "Journal of Anat." vol. vi. p. 242, 1872) states that irritation of the right pneumogastric chiefly causes movement in the duodenum, and irritation of the left, movement in the ileum. Goltz (Pflüger's "Archiv," 1872, p. 616) has shown that in the frog the excitability of the myenteric ganglia is very greatly augmented when, by destruction of the brain and spinal cord or section of the pneumogastrics, they are cut off from the central nervous system, which therefore in this animal appears to exert an inhibitory influence upon them.

either of the peripheral extremities of the splanchnic and vagi, of the solar plexus, of the ganglia of the myenteric plexus, or possibly even of the muscular fibres themselves, by the carbonic acid or other product of disintegration, which accumulates in the stagnating blood. They maintain that when such products are present, lively movements can be induced by irritation either of the splanchnics or of the pneumogastrics; but that when absent, no amount of irritation of these nerves has any effect. Both nerves, therefore, contain motor fibres for the intestines, which, however, only act under certain conditions.* Hermann† remarks simply that saturation of the blood with oxygen arrests the movements of the intestines, whilst saturation with carbonic acid excites them, which explains to some extent their activity shortly after death. The whole subject requires to be reinvestigated, since Horvath‡ has shown that temperature has a very powerful influence in determining the reaction of the intestinal walls to electric stimulation. No movements occur in the intestines according to this observer, when they are cooled below 66° F., whilst they exhibit spontaneous movements, and contract on the application of electricity between 66° F. and 106° F., at which last temperature the movements are sometimes very vigorous and rapid, supporting in Rabbits and Guinea-pigs a column of water 18 cm. in height. Horvath, in opposition to the statements of Nasse, Legros, and Onimus and Mayer, maintains that a certain fulness of the vessels is absolutely necessary; no contractions occurring in anæmia even at a high temperature. The action of many aperient medicines, as Senna and Croton oil, has been demonstrated§ to be due to their producing increased peristalsis; if pushed too far, however, and if their action be very violent, they diminish the irritability of the intestines and even cause paralysis, a fact not to be overlooked in the administration of purgatives for the relief of constipation. Saline aperients, if given in a sufficient state of concentration, probably act chiefly by producing diosmosis; but partly also by causing increased secretion—not by increasing peristalsis.‖ Certain poisons excite lively intestinal movements. Nasse observed that injection of nicotin and of sulphocyanide of potassium caused violent tetanic spasms of the small intestines in rabbits. Opium acted but slightly, and strychnia and curare were totally inoperative. Carbonic acid intoxication caused general contraction, but no active movements of the walls of the intestines.

100. The rapidity with which the food traverses the intestinal tube is subject to great variations. A comparison of observations made on patients suffering from fistula in different regions of the alimentary canal shows that part of the food passes rapidly through the stomach into the intestines, but that having

* It is to be noted, however, that although the absence of arterial blood causes lively contractions, none are produced by an excess of venous blood in the mesenteric veins, such as may be occasioned by pressure on the vena portæ. This fact is admitted by Mayer and Basch, and has also been demonstrated by Legros and Onimus (Robin's "Journal de Physiol.," 1869, pp. 37 and 163). It should also be stated that Van Braam Houckgeest (Pflüger's "Archiv," 1872, p. 298), who operated carefully by opening the abdomen whilst the animals experimented on were immersed in water containing 0·6 of common salt, at blood heat, maintains that anæmic conditions prevent, arrest, or weaken the movements of the intestines, and that whilst distension of the vessels with *either* arterial or venous blood favours contraction in the *small* intestines, the latter condition alone seems to increase the irritability of the the nervo-muscular apparatus of the *large* intestines in Rabbits. Sanders Ezn (Humphry and Turner's "Journal of Anat.," vol. vi. 1872, p. 424), operating in the same way as Houckgeest, maintains that the amount of blood in the vessels has no influence on the intestinal movements.

† "Physiologie," 1874, p. 136. ‡ "Centralblatt f. d. Med. Wiss.," 1873, p. 597 *et. seq*

‖ Legros and Onimus, *op. cit.*

reached the duodenum it traverses that and the following segments of the intestines comparatively slowly. Thus, in a case of duodenal fistula in a man, recorded by Kühne,* portions of uncoagulated milk, and small fragments of meat, were observed to make their appearance within ten minutes of their being swallowed. So, too, in a case of artificial anus which opened into the upper part of the jejunum, reported by Dr. Busch,† the first portions of food usually appeared in from 15 to 30 minutes after ingestion. But in another case reported by Dr. Braune,‡ in which the artificial anus communicated with the intestine a few inches above the ileo-colic valve, the first appearance of the food did not present itself earlier than two hours and a quarter after ingestion, and the last not until about six hours after, so that we may consider the time occupied by the food in traversing the small intestine, to be about 3 or 4 hours. The food having traversed the small intestine, enters the cæcum by an aperture guarded by a valve (the Ileo-cæcal), whose lateral position is clearly a provision for preventing the whole weight of the Fæces, as the remains of the food here begin to be called, by which it might be forced back, from resting upon it. The Fæces here propelled forwards more slowly are in their ascent lodged in the sacculi of the colon, by which they are supported during the intervals of the peristaltic action of the Muscular Coat. In their course through the descending colon, they pass through its remarkable sigmoid flexure, by which they are prevented from directly pressing against the anal orifice.§ According to the observations of M. Voit,‖ in cats and dogs the evacuation of fæces, known by their characters to proceed from particular kinds of food previously given, almost invariably occupies 24 hours.

101. On examining the outlet by which the fæces are voided, we find that it is placed, like the entrance, under the guardianship of a ganglionic centre described by Masius, termed the ano-spinal centre, situate in the lower part (opposite the 6th lumbar vertebra in the Rabbit) of the Spinal Cord; subject, however, to some control on the part of the will. In the lowest animals, the act of discharging excrementitious matter is probably as involuntary as are the acts immediately concerned in the introduction of nutriment; and it is performed as often as there is anything to be got rid of. In the higher classes, however, such discharges are much less frequent, as reservoirs are provided, in which the excrementitious matter may accumulate in the intervals. The associated movements required to empty these are completely involuntary in their character, and are excited by the quantity, or stimulating quality, of the contents of the reservoir. But, had volition no control over them, great inconvenience would ensue; hence, sensation is excited by the same stimulus which produces the movements, in order that, by arousing the will, the otherwise involuntary motions may be restrained and directed. There can be little doubt, from the experiments of Dr. M. Hall, as well as from other considerations, that the associated movements by which the contents of the rectum and bladder are discharged, correspond much with those of Respiration; being in their own

* "Physiologische Chemie," 1868, p. 53. † Virchow's "Archiv," Band xiv. p. 140.

§ For some further observations on Defæcation, the reader is referred to O'Beirne, "New Views of the Process of Defæcation," Washington, 1834; and to vol. ii. p. 406, of Dr. Austin Flint's "Physiology of Man," both of whom agree in believing that under ordinary circumstances the rectum is contracted and contains neither fæces nor gas, whilst the condition which immediately precedes the desire for defæcation is probably the descent of the contents of the sigmoid flexure of the colon into the rectum. They admit, however, that under certain circumstances fæces must accumulate in the lower and dilated portion of the rectum.

‖ "Zeits. f. Bilogoie," Band ii. p. 6.

nature excito-motor, but being capable of a certain degree of voluntary restraint and assistance. The act of Defæcation (as of Urination) chiefly depends upon the combined contraction of the abdominal muscles, similar to that which is concerned in the expiratory movement; but, the glottis being closed so as to prevent the upward motion of the diaphragm, their force acts only on the contents of the abdominal cavity; and so long as the sphincter of the cardiac orifice of the stomach remains closed, it must press downwards upon the walls of the rectum and bladder—the contents of the one or the other of these cavities, or of both, being expelled, according to the condition of their respective sphincters. These actions are doubtless assisted by the contraction of the walls of the rectum and bladder themselves, for we sometimes find their agency sufficient to expel the contents of the cavities, when there is a total paralysis of the ordinary expulsors, provided that the sphincters be at the same time sufficiently relaxed.* This is more especially the case when their power is augmented by increased nutrition. For example, in many cases of disease or injury of the Spinal Cord the bladder ceases to expel its contents, through the interruption of the circle of reflex action; but after a time, the necessity for drawing off the urine by the catheter is found to exist no longer, the fluid being constantly expelled as soon as it has accumulated in small quantities. In such cases, the mucous coat is found after death to be thickened and inflamed, and the muscular coat to be greatly increased in strength, and contracted upon itself. It would seem, then, that the abnormal irritability of the mucous membrane, dependent upon increased development and activity of local ganglionic centres, and the increased nutrition of the muscular substance which appears consequent upon this, enable the latter to expel the urine without the assistance of the ordinary expulsors.

102. On the other hand, the sphincters which antagonize the expellent action are usually maintained in a state of moderate contraction, so as to afford a constant check to the egress of the contents of the cavities; and this condition has been fully proved to result from their connection with the lower part of the Spinal Cord, ceasing completely when this is interrupted. But the sphincters are certainly in part controlled by the will, and are made to act in obedience to the warning given by sensation; and this voluntary power is frequently destroyed by injuries of the Brain, whilst the Spinal Cord remains able to perform all its own functions, so that discharge of the urine and fæces occurs. In their state of moderate excitement, the expulsors and the sphincters may be regarded as balancing one another, so far as their reflex action is concerned, the latter having rather the predominance, so as to restrain the operation of the former. But, when the quantity or quality of the contents of the cavity gives an excessive stimulus to the former, their action predominates, unless the will be put in force to strengthen the resistance of the sphincter; this we are frequently experiencing, sometimes to our great discomfort. On the other hand, if the stimulus be deficient, the will must aid the expulsors, in order to overcome that resistance which is due to the reflex contraction of the sphincters; of this also we may convince ourselves, when a sense of propriety, or a prospective regard to convenience, occasions us to evacuate the contents of the rectum or bladder without a natural call to do so.

4. *Of the Changes which the Food undergoes during its passage along the Alimentary Canal.*

103. The object of the Digestive process, as already pointed-out, is to reduce the Alimentary matters to a condition in which they can be introduced

* A special sphincter has been described by Chadwick ("Gynæcolog. Trans.," 1877, vol. ii. which acts as a detrusor.

by Absorption into the Circulating system. This reduction is partly effected, as we have seen, by Mechanical means; but it is chiefly due to the Chemical agencies which are brought to bear upon the ingested substances, during their transit through the mouth, the stomach, and the upper portion of the intestinal tube. The first of these is exerted by the *Salivary* fluid, which is incorporated with the food in the act of mastication, and of which a large quantity descends with it to the stomach. For the secretion of this fluid, it will be remembered that three pairs of glands of considerable size are provided—namely, the parotid, the submaxillary, and the sublingual. But in addition to these there is a small pair situated just at the tip of the tongue, whilst a very important part of the fluid is furnished by the lingual and palatine glands, and by the numerous follicular glands lodged in and beneath the buccal mucous membrane. The larger Salivary glands are all constructed upon the type of compound racemose glands, the principal features of which are shown in Figs. 64 and 65. The excretory ducts (*d*, Fig. 65), which are lined by columnar epithelium, divide and subdivide till they terminate in a series of follicles, which contain, especially in the submaxillary gland, large centrally-situated transparent cells with flat and eccentric nuclei (*a*, *a*); and, in addition, a mass termed the "semilunar body of Giannuzzi" (*c*),* which appears at first sight to be granular protoplasm with interspersed nuclei, but which later investigations have shown to be composed of many closely-compressed cells in a condition of active growth. The central cells contain mucin, and their nuclei alone stain with carmine. The peripheric cells are albuminous, and both their bodies and their nuclei are thoroughly and completely stained with carmine.† It is believed that the albuminous cells during the period of rest of the gland gradually become metamorphosed, and develop into the mucin-holding cells, which break down or yield up their contents during the period of active secretion, the latter in the meanwhile growing, so as to fill the acinus when the gland is exhausted with dark granular protoplasmic cells. In glands which secrete saliva containing little or no mucin, like those of the rabbit and the parotid of the dog, peripheral cells only are present; and even in the submaxillary gland of the dog there are many acini which contain no central

† Heidenhain, "Studien des Physiolog. Institut. zu Breslau," 1868, Heft 4.

or mucin-holding cells.* Bermann† finds a second gland constructed on the compound tubular type in the submaxillary gland of man and of the rabbit. The ducts are looped and tortuous and open into Wharton's duct, and in a late communication‡ he maintains that in the submaxillary gland of the mouse, bat, cat, and dog, there are three differently constructed glands combined: a true acinous gland; a compound tubular gland with tortuous canals, which are lined by a single layer of epithelium, and have no "semilunar bodies;" and lastly, a simple tubular gland.§ Ewald and others have observed a fine plexus surrounding the individual cells, which they believe to be the origin or ultimate termination of the Salivary ducts.‖ The follicles are surrounded by a rich plexus of blood-vessels, the interstices of which form spaces from which the lymphatics take origin. Pflüger¶ believes he has been able to follow nerve-fibres into direct continuity with the cells lining the acini and ducts of the salivary glands, and describes no less than four modes of termination. In the first (1 and 2,

Fig. 66.

§ Nüssbaum believes that the cells secreting ferment may be distinguished from mucin-cells and from the substance of the gland by the deep brown tint they assume when exposed to the action of osmic acid (Schultze's "Archiv," Band xiii. p. 724). J. N. Langley, on the other hand, denies the correctness of the above statement (Kühne's "Untersuchungen," Band i. 1878, p. 471). See also Grot, in Hofmann's "Jahresber" for 1876, Band v. Th. i. p. 312.

‖ Boll has described an intra-alveolar reticulum of connective tissue, which is perhaps identical with it.

¶ Pamphlet, "On the Terminations of the Secretory Nerves of the Salivary Glands," 1866; and "Medicin. Centralblatt," Nos. 10 and 14, 1866; Kupffer, in Ludwig's "Festgabe," 1875, p. 64; see also Palladino (Abstract in "Centralblatt," 1873, p, 782), who, however,

continuous, whilst the medulla passes on between the gland-cells and divides into finer fibres, each of which, regaining a sheath, perforates the wall of one of the secreting cells and terminates in the nucleus. In the second mode (4, Fig. 67), the nerve-fibres, which probably belong to the *sympathetic system*, terminate in multipolar ganglion cells, some of the offsets or caudate prolongations of which in like manner penetrate the secreting cells and terminate in the nuclei. In the third mode (3, Fig. 67), a nerve-fibre, invested with a sheath containing nuclei, within which are numerous varicose axis cylinders covered by a thin layer of medullary substance, terminates peripherically in a conical enlargement, which he terms a "protoplasma-foot or expansion," and which he regards as a kind of intermediate organ between the nervous and glandular substance. Lastly, he has observed certain nerve-fibres distributed to the cylindrical cells lining the salivary ducts (5, Fig. 67). The attached extremity of these cells is often marked with longitudinal striæ, and is continued for some distance as a varicose prolongation. The nerve-fibres lie beneath the basement membrane, and form exquisitely fine threads, with swellings or varicosities upon them, which he has been able to trace into direct continuity with the above-mentioned prolongations of the epithelial cells, several passing into each cell. The development of the salivary glands commences during the second half of the second month, by a simple solid protrusion of the deeper epithelial layer of the wall of the oral cavity which is invested by a mesodermal layer, that is, a process of the mucosa, and which subsequently gives-off bud-like processes and becomes hollow. The submaxillary gland is the first to appear, then the sublingual, and finally the parotid.

104. *Physical and Chemical Characters of the Mixed Saliva.*—Mixed saliva, the product of the fluids secreted by the several salivary glands and of the mucous glands of the mouth, is a colourless, ropy and spumous fluid, the specific gravity of which varies in man from 1·002 to 1·009. It is more or less cloudy, owing to the presence of epithelial scales thrown off from the buccal mucous membrane, and to a small number of corpuscles which perform curious spontaneous and amœboid movements.* Its index of refraction for light is 1·3354.† It is alkaline, and contains about one-half per cent. of solids, the organic being in rather larger quantity than the inorganic. (For fuller analysis, see APPENDIX.) The most important of the organic substances, and that on which the peculiar properties of the saliva essentially depends, is a *diastatic ferment*,‡ capable of converting starch and glycogen into glycose, but without action on gum, cellulose or pectose. The other organic constituents are *globulin*, which is precipitated when a current of carbonic acid gas is transmitted, and *mucin* with a trace of *albumin*, which renders the fluid cloudy on the addition of nitric acid after the removal of the globulin. The inorganic constituents are chiefly sodium chloride, sodium and calcium carbonates, with phosphates of potassium, sodium, calcium, and magnesium. There are also traces of nitric acid (Schonbein) and of potassium sulphocyanide, the quantity of

was only able to trace *non*-medullated nerve-fibres into the secretory cells of the submaxillary gland in the Horse. Asp (Abstract in "Centralblatt," 1873, p. 565), Mayer, Hering, Krause, Schweigger-Seidel, Henle, Klein, Ewald, and many others, express grave doubts as to the accuracy of Pflüger's statements of the mode of termination of the nerves in the salivary glands, and the subject may be regarded as being still sub judice.

* Brücke, "Sitzber. d. Wiener Akad.," Band xlv.

† Valentin, Pflüger's "Archiv," Band xix. p. 84.

‡ This was formerly termed *ptyalin*, but Hoppe-Seyler recommends the use of the term to be discontinued, as it has been applied to different substances. It is either altogether absent, or exists only in small quantities in the saliva of dogs and horses, but is abundant that of the rabbit and guinea-pig. ("Phys. Chem.," 1868, p. 186.)

the latter amounting to about 0·16 per 1000,* the use of which may possibly be as suggested by Kletzinsky† to prevent the development of bacteria and other low organisms between and in the cavities of the teeth. It appears to be absent in the dog. Though always alkaline when it is being secreted in health, the mixed saliva becomes neutral or even acid if long retained in the mouth, and is often acid in advanced stages of diabetes. It contains a certain quantity of free gas, one hundred cub. cent. of the saliva of the dog yielding about 0·5 per cent. of its volume of oxygen, about 0·7 per cent. of nitrogen, and about 20 per cent. of carbonic acid gas to a vacuum, whilst nearly double that quantity is eliminated on the addition of phosphoric acid.‡

The secretion of the several salivary glands presents well-marked peculiarities both in physical and chemical characters, as was first demonstrated by Claude Bernard, who inserted tubes into the different ducts, and found on placing a few drops of vinegar on the tongue of a dog that the submaxillary saliva was immediately secreted, speedily followed by that from the parotid, and at a later period by that from the sublingual. The fluid discharged by the parotid gland was clear and watery, that of the sublingual thick and viscid, whilst that of the submaxillary was intermediate in this respect to the others. Hence Bernard was led to suggest that the submaxillary gland ministers to the sense of taste, whilst the parotid is subservient to mastication and the sublingual to deglutition. *Submaxillary saliva* is distinctly alkaline, and has a sp. gr. of 1·005, a considerable quantity of mucin, and is active, except in new-born children, in converting starch-paste into dextrin and ptyalose. The diastatic ferment does not appear in it until about the end of the second month, and hence it is unadvisable to give very young children much amylaceous food. Metallic iodides which have been absorbed or injected into the blood appear in the submaxillary saliva in the course of a few minutes, whilst other metallic salts, as potassium ferrocyanide, are not eliminated by this channel. After standing for some time submaxillary saliva deposits calcium carbonate, with some albuminous substance. *Parotidean saliva* is clear, watery, and distinctly alkaline. It contains a little diastatic ferment even in the new-born child,§ and sulphocyanide of potassium, but no mucin, or if any, only traces from minute muciparous glands, which Bernard‖ has shown open into Steno's duct as it traverses the cheek. It presents great variations in the proportions of its solid constituents, the amount of inorganic matter varying more than double, and of organic substances twenty-five-fold.¶ Its sp. gr. varies from 1·0061 to 1·0088. The size of the parotid gland in animals is proportionate to the degree in which the mastication of their food is performed. It is large in the horse, which lives on comparatively dry food, less in Carnivora, and still less in the aquatic mammals. It is absent in birds, which swallow their food whole.** The extreme ropiness of *sublingual saliva* is due to the large amount of mucin present in it. Heidenhain found that it contained 2·75 per cent. of solids. The submaxillary gland is largely developed in the Carnivora, but is

* According to Vierordt, "Anwendung des Spectral Apparat. zur Photometrie," 1873, p. 147, who estimated its amount by measuring the absorption of light in the green and blue portions of the red fluid produced on the addition of iron chloride to the saliva. reduced to a minimum in Birds. In Fishes the larger glands are wholly absent.*

105. Of the quantity of Saliva which is secreted daily it is impossible to form an exact estimate, since it varies greatly with the character of the food ingested, and the frequency with which that food is taken; the secreting process being, indeed, almost suspended when the masticating muscles and tongue are completely at rest, unless excited by a nervous stimulus. The taste, the sight, or even the idea, of savoury food, is sufficient to cause a flow of saliva, especially after a long fast: but it is by the masticatory movements that this flow is chiefly promoted, so that the amount poured-forth will in a great degree depend upon the duration of these movements,—this, again, being governed by the degree in which the food requires mechanical reduction. Harley, with great probability, estimates it at from 1 to 2 lbs. in man. Oehl found the quantity obtained by catheterization from the submaxillary gland, as compared with the parotid, to be as 3 : 1. He obtained 26 grains per hour from a fasting man, and only 15 grains after food had been taken. The influence of the kind of food upon the quantity secreted was well shown by Tuczek,† who found that in adult men, fed exclusively on black bread, the amount of saliva secreted per diem was about 19, with white bread 24 oz., with mixed food 17 oz. With mixed food in an old man the amount was 13 oz., in an old woman 8 oz., and with the same in a child aged 1½ years 5 oz.‡ The influence of sapidity on the amount of saliva is shown by an experiment made by Dr. Dalton,§ in which it was found that meat gained 48 per cent., whilst bread, though so much drier, only gained 55 per cent. of its weight. In M. Oehl's experiments, Salt, Pepper, Vinegar, and Quinine excited the flow of saliva from the parotid and submaxillary glands to about an equal degree. Honey chiefly effected an increase of the submaxillary saliva. Butler Stoney‖ found in a woman with parotid fistula, that the flow of saliva from this gland was stimulated by mastication alone, but much more by the mastication of any sapid substance, especially if acid (tartaric acid). As compared with other glands, the salivary glands perform a large relative amount of work, secreting in the course of one hour, when in full activity, thirteen times their own weight of saliva.¶

106. *Uses of the Saliva.*—Besides the preparation of the food for the ulterior changes which it has to undergo, by promoting its mechanical reduction in the act of mastication, and by facilitating the subsequent admixture of other watery fluids, and besides the material assistance which it affords to the act of deglutition, the Saliva fulfils other and perhaps still more important purposes. Without its solvent action on many of the solid constituents of our food, their taste would be either greatly diminished in intensity or altogether lost. Moreover, by lubricating the surfaces of the mouth and teeth, it prevents the

* Heidenhain ("Ueber die Acinosendrüsen der Schleimhaut, &c., Inaug. Diss.," Breslau, 1870), and more recently Lavdowsky ("Zur feineren Anat. der Speicheldrüsen," Max Schultze's "Archiv," Band xiii. Heft 2), relying on certain peculiarities of the epithelial cells in the cul-de-sacs of the salivary glands, have distinguished two groups which they have named respectively the *mucous* and the *serous* salivary glands. Lavdowsky gives the following classification: *mucous glands*, orbital and suborbital (dog and cat); sublingual (dog, cat, rabbit, and man); *serous glands*, orbital and submaxillary (rabbit); parotid (dog, cat, rabbit, and man).

† "Zeitschrift f. Biologie," Band xii. p. 534.

‡ Lassaigne found on abstracting the Bolus of food, as it passed down the œsophagus in Horses, that 100 parts of green stalks were mingled with 49 parts of saliva, the same quantity of oats and barley with from 113 to 186 parts, and of dry hay with 406 parts of saliva. ("Comptes Rendus," xxi. p. 362.)

¶ Tuczek, "Zeitschrift f. Biologie," Band xii.

adhesion of viscid substances, whilst its presence is of great importance in enabling the tongue to perform the rapid movements requisite for distinct articulation, as is clearly indicated by the thick and almost unintelligible utterance of those in whom from any cause the mouth and tongue have become dry and parched. Lastly, it has a powerful chemical action upon the farinaceous constituents of food, the influence being of the nature of a ferment, so that a small proportion of Ptyalin will convert a considerable, though, according to Paschutin,* not an indefinite quantity of starch into "ferment" sugar. Starch submitted to the action of saliva is first converted into *erythrodextrin*, which is a substance that is stained red by tincture of Iodin, and then into *achroodextrin*, which is not coloured by iodin and sugar; and finally the achroodextrin is converted into sugar, a portion, named *dystropodextrin*† long resisting the action. The sugar thus formed, for which the name "ptyalose" has been proposed, to distinguish it from "glycose" and "maltose,"‡ has only half the power of reducing copper oxide possessed by glycose, whilst it refracts polarized light more strongly. Seegen found about 65 to 70 per cent. of glycogen is converted into ptyalose. If the starch be crude or raw the time required is considerable,§ amounting to two or three days even at blood heat, but the rapidity with which it takes place under favourable circumstances is very great; thus Vintschgau‖ found that if well boiled, thin starch-paste, which had been rendered blue by the addition of Iodin, were added drop by drop to Saliva at a temperature of 98° or 99° F., the colour instantly disappeared; and Dr. Dalton¶ found traces of sugar in starch-paste which had been kept in the mouth within 30 seconds. The action on glycogen is much more slow, and Lawilski** maintains that the salivary diastase has no power of converting pure dextrin into sugar. The temperature at which the action is most intense is at 95° F.,†† or if diluted with ten times its volume of water at a somewhat higher temperature, as from 100°·4 F. to 105°·8 F.,‡‡ whilst it becomes inoperative at 140° F. This power is not peculiar, however, to the Saliva; for Bernard has shown that it is possessed by many azotized substances in a state of incipient decomposition. The presence of a diastatic ferment has been ascertained in man in the saliva secreted by all the glands; but in the dog it is absent in the parotidean fluid, and it exists only in small quantities in the secretion of the other salivary glands, which is in accordance with the nature of the food of this animal. In man, the transforming process is certainly not checked on the passage of the food into the stomach, as it is in the dog, which is partly owing to the larger proportion of Ptyalin his saliva contains, and partly to the acidity of the gastric juice being much less. It would appear that the Saliva has little or no chemical action on either the oleaginous or on the azotized constituents of the food, and its operation on them, if it have any, must therefore be purely physical.

107. *Action of the Nerves upon the Salivary Glands.*—The relations of the nervous system to the salivary glands are peculiarly interesting, and on account of the proximity of these glands to the surface, and the facility with which heir nerves, vessels and ducts can be isolated, they have been studied with

great care by many observers.* In the case of the submaxillary and sublingual glands the sensory or centripetal nerves implicated are the fibres of the Glosso-pharyngeal and of the Fifth pair of nerves, and the secreto-motor, or centrifugal fibres, are branches of the Facial, the fibres of which run in the chorda tympani. In the case of the parotid gland, whilst the sensory channels are the same, the secreto-motor fibres run in the nervus petrosus superficialis minor, from the Facial to the otic ganglion, and then in the auriculo-temporal branch of the Fifth. The centre of reflection is the ganglionic mass in the medulla oblongata corresponding to the nuclei of origin of the Facial and Glosso-pharyngeal nerves. All the glands are supplied, in addition, with sympathetic

N, submaxillary salivary gland; O, sublingual; JM, Wharton's duct: JL, duct of sublingual, each with a canula tied into it; T SS′ lingual branch of the inferior maxillary division of the Fifth nerve; SS′, branches distributed to the mucous membrane of the mouth; F, facial nerve; *c*, chorda tympani; *a*, branch of the Facial distributed to the submaxillary gland after running for a short distance with the lingual of the Fifth; *g*, submaxillary sympathetic ganglion; *q*, superior cervical ganglion; P, branch from this ganglion to the submaxillary gland; *j*, internal maxillary artery; V, vidian nerve; *l*, branch of the lingual nerve ramifying in the buccal mucous membrane.

or vaso-motor fibres, regulating the calibre of the vessels, the ganglia of which are the submaxillary and the sublingual ganglia† for the glands of the same name, and the otic for the parotid. In addition to the vaso-motor fibres, the sympathetic nerves supplying the submaxillary and sublingual glands appear to contain fibres which are secreto-motor, and excite a special kind of secretion. The influence of the nerves may be demonstrated by the following experiments:—If the submaxillary and sublingual glands be cleanly dissected out, they may be seen at rest, secreting little or no saliva, whilst the venous blood returning from them is of a dark tint. If a drop of vinegar be now placed upon the tongue of the animal, the arterial twigs supplying the gland immediately enlarge, the rapidity of the current of blood is increased, the veins pulsate and convey scarlet blood, the pressure of which on their inner

* Bernard (Lectures, "Med. Times and Gaz.," vol. i. 1860, pp. 288–361), Ludwig ("Lehrbuch der Physiologie," Band ii.), Eckhard ("Beiträge," Band ii. p. 205; iii. 1862, p. 41; iv. 1867, Heft 2), Schiff ("Physiologie," 1859, p. 393), Von Wittich (Virchow's "Archiv," Band xxxvii. and xxxix.), Bidder (Reichert and Dubois-Reymond's "Archiv," 1866, p. 339), and Heidenhain, *loc. cit.*

† Some observers, as Sappey, regard the so-called sublingual ganglion to be only a plexus.

surface is considerably increased, and there is an abundant* discharge of limpid, highly-alkaline saliva, containing small quantities of albumin, globulin and mucin. The evidence that these conditions, in the case of the submaxillary and sublingual glands, are the result of the stimulus of impressions transmitted through centripetal fibres of the Fifth and Glosso-pharyngeal nerves to the Medulla oblongata, and there reflected to the glands through centrifugal nerves contained in the chorda tympani, the saliva thus discharged being termed *chorda tympani saliva*, lies in the fact that if the sensory nerves be divided, gustatory impressions no longer cause a flow of saliva, whilst if the *central* or *proximal* cut extremities of the divided nerves be stimulated, an abundant flow is immediately induced. In like manner, after section of the Facial or of the Chorda tympani—which are the secreto-motor nerves—the vessels distributed to the submaxillary and sublingual glands contract, owing to the unopposed action of the sympathetic, the current in them becomes slower, the blood they contain darker, the secretion of Saliva diminishes, and vinegar placed on the tongue no longer excites the secretion; whilst, if the *distal* cut extremities of these nerves be stimulated, all the former phenomena recur. On the other hand, if the sympathetic branches proceeding to the submaxillary and submental glands from the plexus around the facial artery, and primarily from the superior cervical ganglion, be directly irritated, the current of blood becomes very slow in consequence of the contraction of the vessels, its colour in the veins very dark, and the secretion of Saliva, whilst it diminishes in quantity, becomes at the same time cloudy and remarkably viscous, contains more albumin and mucin, and a remarkable number of sarcode-like bodies possessing the power of spontaneous movement, but no increase of inorganic substances.† To this kind of Saliva the term *sympathetic saliva* has been applied. The influence of the sympathetic is regarded by Heidenhain‡ as essentially trophic. That the secretion does not wholly cease after section of the chorda tympani is believed by Bernard to be due to the reflex action of the submaxillary ganglion, but even when the sympathetic fibres are divided, it is not entirely stopped, a small quantity of so-called *paralytic saliva* continuing to be secreted when the tip of the tongue is excited by induced electricity. It is remarkable that if a little atropin be injected into the veins of an animal, stimulation of the chorda tympani is not followed by increased secretion of Saliva, though the dilatation of the blood-vessels occurs as usual. Hence it has been concluded that the Facial nerve contains two kinds of nerve-fibres—one, stimulating the cells to secrete, and the other, acting as dilating or inhibitory fibres upon the blood-vessels.

108. In the case of the parotid gland, the sensory nerves are of course the same as before, but the secreto-motor nerve is the lesser superficial petrosal nerve, for section of this nerve or of the auriculo-temporal branch of the Fifth pair, which the petrosal enters, arrests the secretion of the gland, whilst stimulation of the root of the facial or of the smaller petrosal or auriculo-temporal nerve causes an abundant flow of thin saliva, resembling that secreted by the submaxillary gland when the chorda tympani is stimulated, the vessels enlarging so much that they convey quadruple the amount of blood. The relations of the parotid to the sympathetic differ from those of the submaxillary

* 856 grains in one hour in a dog (Ludwig).

† The secretion that is discharged when a stimulus of gradually increasing intensity is applied to the sympathetic becomes progressively more abundant, and at the same time contains more organic constituents, though if the stimulation be rendered yet stronger, or be simply maintained at a high degree, the saliva becomes thin and limpid and poor in organic constituents.

‡ Pflüger's "Archiv," Band xviii. 1878, p. 1.

and sublingual glands, its stimulation merely causing a diminution in its quantity without effecting any change in the viscidity of the saliva secreted. It is possible that the otic ganglion may be the centre of reflexion without the cerebro-spinal centre being in any way implicated, the sensory impression passing by the Glosso-pharyngeal and the nervus petrosus superficialis minor, and being reflected at the ganglion upon the gland through the auriculo-temporal. Eckhard* maintains that in the *sheep* the Parotid glands act uninter-mittingly, and are not under the influence of any cerebral nerve, since no change was effected in the secretion by stimulation of the fifth, or of the portio dura of the seventh, or of the sympathetic nerve. Division of this last in the neck was also devoid of influence, and no increase in the quantity discharged was produced by brushing the mucous membrane of the mouth with vinegar. An extremely important point in the physiology of secretion has been pointed out by Ludwig, which shows the *direct influence of the nervous system* upon gland tissue and cells apart from any action on the blood-vessels, and that the process of secretion is not one of mere filtration; that if the circulation be suppressed either by ligature of the vessels or by decapitation of the animal, and either the sensory or excito-secretory nerves be irritated, Saliva may still be secreted. He also observed a fact which tells in the same direction—namely, that the pressure under which the saliva is secreted by the submaxillary glands as measured by a canula attached to a manometer, and introduced into Wharton's duct, is greater than the pressure of the blood in the carotids. In the former amounting to 190 mm. of mercury (or nearly 8 inches), whilst in the latter it was only 108·5—112·3 mm. (or about 4½ in.); and lastly he noticed that the temperature of the saliva was 1°·5 C., or nearly 3° F. warmer than the blood of the Carotid artery, a circumstance indicating that active chemical changes are taking place in the gland. The partial *independency* of secretory activity upon increased flow of blood through the gland is further shown by the experiments of Giannuzzi,† in which the glands were paralyzed by the injection into the ducts of a 4·9 per-cent. solution of Carbonate of Soda, or of a 0·5 per-cent. solution of hydrochloric acid. On stimulating the chorda tym-pani all the ordinary vascular phenomena made their appearance, but no increase in the amount of saliva secreted occurred and the gland soon became œdematous, the fluid which should have been used up in the formation of saliva apparently accumulating in the lymphatic system. Obviously, there-fore, secretion is not a purely physical action; and as Ranke‡ remarks, although a large supply of blood affords abundant material for secretion, it is requisite before this act can be accomplished that some change should occur in the gland cells themselves, which it is the special province of the nervous system to induce.§

* Henle and Pfeuffer, "Zeits.," Band xxix. 1867, Heft 1, p. 74.

† "Ber. d. k. sachs Gesells. d. Wiss.," 1865, p. 68.

‡ "Grundzüge der Physiologie," 1868, p. 181.

§ It would appear that there are well-marked differences in different animals in regard to the innervation of the salivary glands. In the *cat*, according to Langley ("Journal of Physiology," vol. i. 1878, p. 96), the effects of stimulation of the nerves are the opposite of those in the dog, the sympathetic secretion being more watery than that of the chorda tympani; the secretory function of the sympathetic nerve as well as that of the chorda being paralyzed by atropin; whilst thirdly, the sympathetic and chorda are not antagonistic for minimal effective stimuli, the apparent antagonistic action of the sympathetic on the chorda for maximal stimuli being probably due to a diminution of the blood supply. It seems, too, either that differences exist between the submaxillary gland of different rabbits or between the gland at different times, since Nüssbaum finds a diastatic ferment constantly present in it, whilst both Grützner and Schiff have been unable to recognise this ferment, either in the extract or in the secretion (Nüssbaum, Schultze's "Archiv," Band xiii. p. 724, and P. Grützner, Pflüger's "Archiv," Band xvi. 1877, p. 105). Perhaps, however, as Grützner suggests,

Heidenhain* has described at length the changes which take place in the salivary glands which have been excited to secrete for a considerable time by irritation of their nerves. These changes consist in the breaking down of the large mucin-holding salivary cells to furnish the secretion, and their replacement by a growth of small granular cells, which he believes to take place from the protoplasmic "semilunar" body of Giannuzzi (*c c*, Fig. 65); Ranvier,† however, whilst admitting that the secretion proceeds from the large cells, maintains that they do not entirely break down, but merely yield up their contents, their nuclei and the protoplasm surrounding the nuclei remaining to repair the loss.‡

To recapitulate—the several conditions under which a flow of saliva may be made to occur, are—1. By the reflex action of the medulla oblongata, the submaxillary and otic ganglia, excited by impressions conveyed through the glosso-pharyngeal and gustatory of the fifth, and taking effect through the motor branches of the facial, running in the chorda tympani and auriculo-temporal nerves. 2. By calling into play the muscles of mastication, the effect being probably due to coincident excitation of the nerves supplying the glands with those distributed to the muscles. 3. By mental stimuli, as by the sight or thought of sapid food. 4. By poisons circulating in the blood, as Camphor, Curare in small doses, Physostigmin, Pilocarpin, the Calabar bean, Chloroform, and the Salts of Mercury. 5. By lesion of certain parts of the encephalon, as the floor of the fourth ventricle, and the cortical substance of the hemispheres near the *sulcus cruciatus*;§ by stimulation of the upper extremities of the sympathetic or pneumogastric nerves divided in the neck, or of the central extremity of the divided sciatic or any other afferent nerve,‖ which is not due (entirely at least) to the effects of this irritation in producing increase of blood pressure. If the stimulation of the sciatic be continued for more than a minute or two, an inhibitory influence is excited on the secretion.¶ The chorda tympani appears to contain fibres exciting an inhibitory action on the blood-vessels, as well as motor fibres inducing secretion. For it has been shown by Heidenhain and Kenchel that after the administration of atropin or daturin, if the chorda tympani be stimulated, the vessels dilate, permitting a freer current of blood through the gland, although there is no increase in the amount of saliva secreted. The submaxillary gland responds much more readily to the electric stimulation of its secreto-motor nerves than the parotid.** 6. By nausea.

109. On its entrance into the Stomach, the food is subjected to the operation of the *Gastric Juice*, which is secreted by the follicles in its walls, or by a certain part of them. This follicular apparatus is extremely extensive, and

Nüssbaum may have excised small portions of the parotid gland, which is very active in effecting the conversion of starch into sugar. Both Grützner and Nüssbaum find that the cells of Acini are only slightly, whilst those lining the duct are intensely blackened with osmic acid.

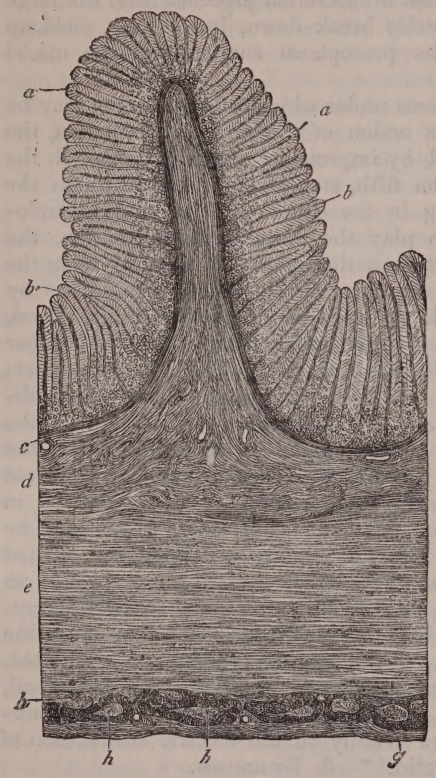
** Bernard, "Leçons de Physiologie Opératoire," 1879, p. 535.

makes up the chief part of the thickness of the gastric mucous membrane. The matrix of the mucous membrane of the stomach in which the glands are imbedded consists of adenoid tissue, or a fibrous network containing cells and nuclei. This is more dense in some parts than in others, which has led various observers to admit the existence of lenticular or solitary glands in the region; but these spots differ from the lenticular glands, in being destitute of a limiting membrane.* The interior surface of the stomach, thrown by contraction when the viscus is empty into irregular folds or rugæ (Fig. 70, A), presents throughout the greater part of its extent, and especially near the Pylorus, small vascular processes or prolongations of the mucous membrane (B),† resembling the villi of the small intestine, of which they must be considered as the rudimentary condition, but differing essentially from them in the circumstance that they contain no lacteal vessels. If the mucous membrane be divided by a section perpendicular to the surface, it is seen to be almost entirely composed of a multitude of parallel tubuli closely applied to each other, their cæcal extremities abutting against the muscularis mucosæ, and their open ends being directed towards the cavity of the Stomach. Between the tubuli, blood-vessels pass up from the submucous tissue, and form a vascular network on its surface, in the interspaces of which the orifices of the tubes are seen.

Fig. 69.



Transverse section through the *fundus of the stomach* in a child.—*a*, *a*, columnar epithelium: *b*, *b*, peptic gland tubes: *c*, muscularis mucosæ, about 1-250th of an inch in thickness, chiefly composed of longitudinal fibres: *d*, submucous tissue; *e*, circular muscular layer; *g*, peritoneum; *h*, ganglia of Auerbach.

The *Septa* contain the blood-vessels (*a*, *a*), and form polygonal meshes around the tubuli. They project some distance beyond the orifices of the tubes into the cavity of the stomach, and form the prominent folds or "plicæ villosæ," which, when the membrane is inspected with the naked eye, or with a lens of low power, give to it its trellis-like aspect.

These tubular glands, the number of which is estimated by Sappey at nearly five millions,‡ do not everywhere present the same structure. Krause,§ who has described the glands with great care, distinguishes simple and compound gastric glands and pyloric glands. In each of the *simple glands* he dis-

* See Klein, *op. cit.*, 548.

† This fact was first brought into prominent notice by Dr. Niell, in his Memoir 'On the Structure of the Mucous Membrane of the Human Stomach,' in the "Amer. Journ. of Med. Sci.," Jan. 1851.

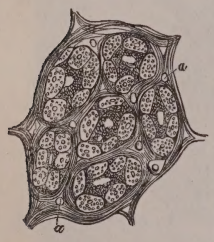
that investing the plicæ, with a few interspersed goblet-cells. The oval nuclei of these cells are situated near their attached ends, and between these extremities are found small protoplasmic masses destined to supply the place of detached or disintegrated cells. The *neck*, which succeeds, is narrower and not so long as the mouth. It is narrower also than

the body. In it the cylindrical cells become successively shorter, till they assume an almost polygonal form. A few conical cells lie in the axis of the tube at this part. In the *body* and *cæcal extremity* two very distinct forms of cells can be recognized: the peptic cells, which are in contact with the membrane, and are large spheroidal or polygonal in form, destitute of cell-wall,* colourless, with darkly granular protoplasm, and containing one or sometimes two oval nuclei; the other occupying the centre of the tube, conical in form,† smaller in size, closely applied to each other, and somewhat indistinct, faintly granular, destitute of cell-wall, and containing a small spherical nucleus. The conical cells form a tolerably uniform layer near the axis of the tube, but some lie free in the channel, and near the cæcal extremity become rather larger, almost attaining to the size of the polygonal cells. The reaction of the different kinds of cells to colouring agents varies considerably, the large polygonal cells staining most deeply with Carmine, Hæmatoxylin, Anilin, and Potassic bichromate, whilst the ordinary columnar cells are less deeply tinged, and the conical cells least of all. The protoplasm of the polygonal cells clears up on the addition of 0·5 to 5 per cent. solution of acetic, or ·002 to ·005 of nitric acid, whilst that of the conical cells becomes more cloudy. It then, however, takes anilin blue, becoming more deeply tinged during fasting than in hunger. Both kinds contain various albuminous bodies, but no mucin.

The *compound gastric glands* (Fig. 71) are scattered throughout the stomach, but are especially abundant in the cardiac extremity. In these the simple excretory duct soon widens, and near the attached surface of the mucous membrane gives off from three to eight cylindrical slightly tortuous cæcal processes. In other respects they exactly resemble the simple gastric glands. If a transverse section be made (Fig. 73) through a cluster of cæca, discharging their contents by a single orifice, they are found to be held together by delicate areolar tissue, a thicker layer of which surrounds the whole, and, forming a kind of septum, isolates them from those of the adjoining glands.

Fig. 73.



Transverse section passing through a cluster of gastric cæca, separated and surrounded by fibrous tissue; *a*, *a*, orifices of divided capillaries.

The *pyloric* or *mucous glands* resemble the compound gastric glands, but the lumen of the tubes is wider, and although the epithelium is exclusively columnar, conical or polygonal cells being entirely absent, yet the cells present the reactions of the conical cells of the compound gastric glands.

Lastly, certain *acinous* glands are contained in the mucous membrane. These are round or oval bodies about 1-50th to 1-25th inch in diameter. They project into the submucosa, and are lined by a low columnar epithelium. They may be regarded as a more complicated form of the compound gastric or pyloric glands, between which and themselves many transitional forms may be found. At the free border of the pyloric valve the pyloric glands cease suddenly, and are replaced by the acinous glands. Klein has shown that the several forms of glands are connected by so many intermediate forms, that it is impossible to draw a very definite line between those secreting mucus

exclusively, and those which produce both pepsin and mucus.* According to M. Cl. Bernard,† when the stomach is empty, the columnar-epithelium which lines the neck of the glands completely blocks-up their orifices, so that during fasting these appear as slightly prominent papillæ; but when the secretion of gastric fluid commences, this epithelium is cast-forth by the pressure from beneath. The *lymphatics* of the stomach‡ form two layers, a superficial and close network, often with sinus-like dilatations, surrounding the cæcal extremities of the peptic glands, and a deeper layer with larger meshes lying in the submucous areolar tissue, and separated from the first by the thin stratum of unstriated muscular fibre, known as the *muscularis mucosæ*, through which many vessels connecting the two strata pass. The *nerves* of the stomach are derived from the pneumogastrics, or rather from the branch of the spinal accessory on each side that joins the pneumogastric, and from the solar plexus of the great sympathetic. They are divided into two layers; one of which forms a plexus in the submucous tissue (Meissner's plexus), whilst the other lies amongst the fasciculi of the longitudinal muscular coat (Auerbach's plexus; Fig. 69, *h*). In the former, ganglia are somewhat sparingly distributed; in the latter, they are abundant.§

110. The nature and composition of the *Gastric Juice* which is secreted and poured forth by the peptic follicles have been the subject of much discussion among Chemists. When obtained without admixture with saliva, it is a clear, transparent, colourless or slightly-yellow fluid with very little viscidity. Its sp. gr. is 1·001 to 1·010. It is not rendered cloudy by being boiled. Microscopic examination indicates the persistence of a few of the cells exuviated from the interior of the gastric follicles; but these for the most part leave no other traces than their nuclei and a fine molecular matter arising from their disintegration. The proportion of solid matter which the Gastric Juice contains is about 0·5 per cent., of which rather more than half is organic substances, and less than half mineral constituents, the chief of the latter being sodium, potassium and calcium chloride, and the phosphates of calcium, magnesium and iron. It is estimated that the total quantity secreted per diem is about one-tenth of the body weight; but it is difficult to give even an approximative estimate of the quantity of fluid poured forth from the walls of the stomach, since it is certain that it varies considerably, according to the nature of the substances ingested. Corvisart, from experiments on dogs,‖ estimated it at about 1-20th of the

* The best accounts of the structure of the mucous membrane of the stomach, and of the gastric glands, are given by Messrs. Todd and Bowman, "Physiological Anatomy," vol. ii. pp. 190 *et seq.*; by Prof. Kölliker, "Mikros. Anat.," Band ii. § 163; by Henle, "Eingeweidelehre," p. 152; by Dr. Klein, Stricker's "Histology," 1870, p. 543: Krause, "Allgemeine Anatomie," 1876; and by Sappey, "Traité d'Anatomie Descriptive," vol. iv.

weight of the animal per diem; Harley,* at 1-15th; Lehmann, at 1-10th; whilst Gruenewaldt† obtained nearly $\frac{3}{4}$ lb. avoird. from a woman of 116 lbs. weight, with a gastric fistula, in fifteen minutes; and Schmidt‡ gives as the mean of experiments on the same woman, about 9000 grains hourly during active digestion.

111. The most characteristic feature of the Gastric Juice is its decided *acidity*, which is very perceptible to the taste, and is constant throughout the animal kingdom. In man, the acidity of the juice when secreted under the influence of mechanical irritation, or of some not very readily soluble substance, as cartilage, after long fasting, is invariably due to the presence of hydrochloric acid. This is probably in combination with some feeble base as glycocol or leucin, the proportion being 0·2 per 1000, but when digestion of ordinary mixed food is taking place, lactic, butyric, and acetic acids may be found in addition, due to the fermentation and decomposition of fats, milk, saccharine and albuminous compounds. Even in the pure gastric juice after standing for some time an organic acid, presumably sarcolactic acid, is developed.§

* "Medico-Chirurgical Review," 1860, p. 211.

† Quoted by M. Edwards, "Leçons," t. vii. 1862, p. 24.

‡ "Annal. der Chemie," von Liebig und Wöhler, vol. xcii. p. 42.

§ Richet, "Du suc gastrique," in "Journal de l'Anatomie," 1878, p. 278, *et seq.* Heidenhain (Pflüger's "Archiv," Band xix. 1879, p. 148) obtained the gastric secretion of the dog nearly pure by isolating a portion of the fundus of the stomach, and found that in that animal it contained on an average as much as 5·2 parts per 1000 of hydrochloric acid. Much discussion has been carried on amongst chemists in regard to the nature of the acid of the gastric juice. The experiments of Berzelius ("Annal. d. Chemie. et de Phys.," 1813, t. lxxxviii.) seemed to show that the acid might be lactic; and Chevreul (see Milne-Edward's "Leçons sur la Physiol.," t. vii. p. 25) and Leuret and Lassaigne arrived at the same conclusion. Prout ("Phil. Trans.," 1825), however, early maintained that it was hydrochloric acid. Tiedemann and Gmelin ("Traité de la Digestion," 1826) thought it was acetic acid. Frerichs (Wagner's "Handwörterbuch," t. iii. p. 780) that it was butyric; and Blondlot ("Traité Anat. de la Digest." 1841, p. 214) that it was the acid calcium-phosphate. Even recent experiments are contradictory. M. Rabuteau ("Bullet. de la Soc. de Biol.," 1874, pp. 96 and 400; see also Tardieu and Roussin, "Les Empoisonnements;" and Dragendorf, "Manuel de Toxicol.," 1874, p. 486) treated gastric juice with quinine, and then extracted the salt of quinine thus formed with amylic alcohol. Under these circumstances the salt obtained was always the hydrochlorate, and not the lactate of quinine. M. Laborde ("Mem. de la Soc. de Biol.," 1874, p. 63, and "Gaz. Med. de Paris," 1874, No. 9) on the other hand has shown that water acidulated with 3 parts in 1000 of hydrochloric acid is capable of converting starch into sugar when the mixture is heated to 150° C, under a pressure of five atmospheres; but the gastric juice is incapable of effecting this change under the same circumstances. Reoch ("Journ. of Anat. and Phys.," vol. xiv. p. 274) admits the presence of hydrochloric acid with traces of lactic acid, on the ground that potassium sulphocyanide, mixed with citrate of iron and quinine, changes colour on admixture with gastric juice, owing to the formation of iron sulphocyanide, a change which is induced by mineral, but never by organic acids. Szabó ("Zeits. f. Phys. Chemie.," 1877, p. 140) finds that both acids are often coincidently present, but that in dyspepsia hydrochloric acid is absent. The latest observer, C. Richet ("Journ. de l'Anat, et de la Physiol." Année xiv., 1878, p. 213) adopting a special method of procedure, suggested by Berthelot, in which ether is employed as a vehicle to abstract the acid from the juice, arrives at the conclusion that there is only one acid, and that one containing cholorin, and therefore probably hydrochloric in combination with some feeble base as leucin or glycocol, no lactic acid being demonstrable, though there may be a trace of sarcolactic acid. That the acidity of the gastric juice is attributable to lactic acid has been maintained by Huhnefeld (Valentin's "Repert für Anat. Phys.," 1841, p. 287), Thomson ("Lond., Edin. and Dublin Phil. Mag." 1841), Lassaigne ("Journal de Chem. Med.," 1844, p. 183), Lehmann ("Ber. d. Gesells. der Wissenschaften," Leipzig, 1847), Heintz (W. Heintz "Pharm. Chem. Centralblatt," 1849, and "Jenaische Ann. für Phys. Med.," 1849, p. 222), Claude Bernard ("Lec. d. Phys. exper. appliquée à la Méd.," t. ii., 1856), Laborde ("Nouvelles Recherches de Gaz. Méd. de Paris," 1874, No. 32–34), and Dionys Szabó (Szabó, "Zeits. f. Physiol. Chemie.," Band i., 1877–78, p. 140). This last-named experimenter adopted several modes of procedure, the more important of which were those suggested by

Dr. F. G. Smith,* on examining the contents of the stomach of Alexis St. Martin, two and a half hours after a small quantity of bread had been eaten, obtained evidence of the presence of lactic, and of the absence of all but the slightest trace of hydrochloric acid. To explain the discrepant results obtained by various observers, allowance must be made for differences existing in different animals, and perhaps also at different ages, since M. Wasmann† has remarked that the pepsin of the stomach of the pig is entirely destitute of the power of coagulating milk, although the pepsin of the stomach of the calf possesses it in a very high degree; from which he is led to suppose that the power of the latter depends upon a particular modification of pepsin, or perhaps upon another substance accompanying it, which ceases to be formed when the young animal is no longer nourished by the milk of its mother (see p. 70, vi.).

112. The peculiar organic constituent of the Gastric Juice, to which the name of *Pepsin* (p. 69) has been given, is not an albuminous substance but a hydrolytic ferment, and appears to be secreted and stored up in the small or adelomorphous cells of the stomach in a neutral state during the intervals of digestion, and to be only mingled with the acid at the moment of discharge.‡ At the commencement of the digestive process the small cells have been observed to swell and to become transparent, and they then contain much pepsin, but in the later stages of digestion they shrink and present a cloudy aspect, and at this period have a much smaller amount of the ferment in their interior. It is probable that whilst chiefly formed in the smaller cells of the peptic glands a small quantity of pepsin is secreted also by the mucous glands;§ but no appearances have been observed favouring the idea that the small cells undergo conversion into the larger delomorphous cells. If the stomach of an animal be thoroughly washed with water till all trace of acidity is removed, a fresh portion of pepsin, possessing a perfectly neutral reaction, can be obtained on further maceration; and Bernard found that on injecting successively lactate of iron and ferrocyanide of potassium into the jugular vein of a rabbit, no blue discoloration of the blood, secretions or tissues generally was observable on account of their alkaline reaction, though this could be immediately produced by the addition of sulphuric or other acid. On examining the stomach, however, he found that whilst the gastric follicles were free from colour, the surface of the mucous membrane was uniformly tinted. From these experiments, the inference may be fairly drawn that whilst the pepsin of the gastric juice is secreted by the cells lining the gastric follicles, the acid is formed, or at least excreted, by the most superficial

Rabuteau and by Baumann. Rabuteau's method of determining whether lactic or hydrochloric acid is present in a fluid, consists in mixing a solution of potassium iodate with the starch paste, and adding a little potassium iodide. If this fluid contain free hydrochloric acid iodin is set free, and the starch is tinted blue; lactic acid, however, in the proportion of 1·1000 sets no iodin free, and consequently causes no change of colour. Baumann's method consists in adding potassium phenyl-sulphate to the fluid or juice. If hydrochloric acid be present, Phenol is given off on distillation, which is easily recognised by a solution of bromin. Lactic acid in the proportion of 1·1000 causes no such decomposition. There are cases indeed perhaps occurring in dyspeptics, in which the gastric juice contains no hydrochloric, but only lactic acid. And, on the other hand, in some instances the gastric juice contains only hydrochloric acid.

cellular layers of the mucous membrane.* The quantity of pepsin that is discharged from the body is probably very small, reabsorption taking place as it traverses the alimentary canal.† It is found in nearly all the muscles and in the blood of the pig, but only traces can be found in the urine of that animal. If the whole of the gastric juice be allowed to drain away through a gastric fistula, the urine becomes alkaline in consequence of the absorption of the alkaline fluids of the intestine.

113. All the more recent and accurate experiments of those who have studied the chemistry of digestion lead to the conclusion that the solvent powers of gastric juice are chiefly exerted upon albuminous compounds, and that its action is comparatively slight upon farinaceous, saccharine and oleaginous substances. Peptic digestion is essentially an acid digestion or a digestion of solution, and it seems to stand in the place of a high temperature and a powerful oxidizing agent. When an albuminous substance, such as white of egg, fibrin, or casein, is exposed to the action of the gastric juice, it swells up, softens and dissolves, becoming converted into some modification of a substance termed *peptone;* this, though varying with the form of albumin from which it is derived, differs from albumin in being no longer precipitable from its neutral solution by any change in the reaction, and in having acquired the power of passing through an animal membrane. It has been ascertained that peptones are capable of maintaining life,‡ and there is evidence to show that soon after entering the blood they are reconverted into albumin; the object of the change of the colloidal albumin into the crystalloid as peptone being to facilitate the entry of the albuminous compounds into the blood. In the subjoined note the principal features of the peptones are given.

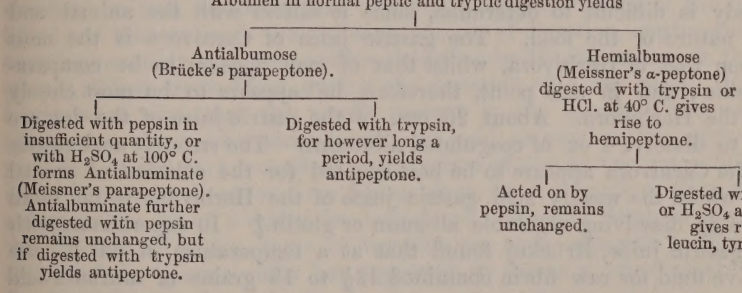
Peptones.—The term peptones is applied to the substances that immediately result from the action of hydrochloric and sulphuric acids, of trypsin or of gastric juice, on albuminous compounds. In order to prepare one form, Hofmann ("Lehrbuch der Zoochemie, 1878, p. 332) recommends fresh, finely-divided fibrin to be macerated with five or six times its volume of dilute hydrochloric acid (containing two parts in 1000). As soon as the fibrin has become gelatinous a little pepsin dissolved in glycerin is poured over it, and it is kept in a water bath, at a temperature of 50°—60° C. (122°—140° F.). Large bubbles form, and in the course of a few hours an opalescent solution is obtained, in which a few fibrinous flocculi float. This is strained and neutralized with sodium-carbonate, so that blue litmus-paper is feebly tinted of a violet colour. The precipitate is allowed to settle, and the fluid is filtered, slightly acidified, heated, and again filtered. Peptone is then thrown down by absolute alcohol, and all fat removed from it by washing with alcohol and ether. It is now macerated for two or three weeks in absolute alcohol to remove the last traces of unchanged albumin. The white mass, freed from alcohol, is dissolved in a little warm water, precipitated by absolute alcohol, and the precipitate is finally dried *in vacuo* at a temp. of 30° C. (86° F.). Fresh peptone thus obtained is a white curd-like substance, which, whilst still moist, changes at a temp. of 80°—90° C. (177°—194° F.) to a yellowish fluid, resembling melted fat, which hardens on cooling. Dry peptone is a yellowish-white, transparent, amorphous, friable, hygroscopic substance, soluble in water, especially if slightly warmed, the solution possessing levo-rotatory power on a ray of polarised light. If long kept, or if it has been dried over 30° C. (86° F.) it dissolves with more difficulty. Though insoluble in absolute alcohol it dissolves in spirit of wine, in proportion to the amount of water present in the fluid. The watery solution is neutral, has a levo-rotatory power, and diffuses easily through all animal and vegetable

* Schiff considers that, as in the case of the Pancreas, a kind of "charging" of the glandular follicles occurs during the intervals of digestion, the pepsin being derived from certain peptogenic materials in the blood supplied by the previous digestion of albuminous compounds, or of dextrin. This view is strongly opposed by Fick ("Verhand. d. phys. med. Gesells.," N.F., Band ii. 53), who found that the stomach of a dog secreted active gastric juice fifteen hours after the last full meal, and that in rabbits, fasting did not diminish the digestive activity of the stomach, whilst the ingestion of dextrin did not augment it.

† Brücke, "Vorlesungen," p. 295; Schiff, op. cit., vol. ii., "Leçon," xxi.

‡ Plósz, Pflüger's "Archiv," Band ix. p. 325.

membranes, in which respects it stands in strong contrast to all the albumins, from which it further differs in not undergoing coagulation at 100° C. (212° F.) and in the precipitate which is thrown down in its solution by concentrated nitric acid, aceto-ferrocyanide of potassium and neutral alkaline salts being redissolved on the application of a gentle heat. They are precipitated by both acetates of lead, and from an acid solution by the biliary acids. They are also thrown down by tannic acid, potasso-mercuric iodide, basic acetate of lead, phosphor-wolframic and phosphor-molybdic acids. On the addition of a little sodium-hydrate to its solutions in water, and then of a drop or two of an extremely dilute solution of copper-sulphate, a rose-red tint is produced (von Gorup-Besanez, "Biuretreaction"). On the addition of concentrated sulphuric acid to the solutions of both gastric and pancreatic peptones the liquid is coloured bluish-violet, with a green fluorescence, and an absorption band appears between *b* and *F*. Nitric acid disturbs this reaction, and the addition of salt makes it more distinct (Adamkiewicz's test). The statements just made in regard to fibrin-peptone hold good in all essential respects for the peptones obtained from other albumins. They all have a strong disposition to form salt-like combinations with very different neutrals. The composition of peptone from fibrin, according to Kossel,* is C 48·97, H 7·06, N 15·14, S 1·16.† *Parapepton* or A-pepton, *Dyspepton* or B-pepton and *Metapepton*, or C-pepton are peptones obtained by Meissner, of which the first is precipitated by nitric acid and by potassium ferrocyanide, the second by potassium ferrocyanide alone, and the third by neither of these reagents. According to Brücke, metapepton is composed of two substances, *hydrophyr*, which is soluble in water, and *alkophyr*, which is soluble both in water and in alcohol. Leucin and tyrosin are amongst the terminal products of gastric digestion. Kühne's (Verhand, "Nat. Hist. Med. Ver." Heidelb., 1876) view of the disintegration of proteids under the action of the digestive fluids may be understood from an inspection of the accompanying scheme :—



Albumen in normal peptic and tryptic digestion yields
Antialbumose (Brücke's parapeptone).
Hemialbumose (Meissner's α-peptone) digested with trypsin or HCl. at 40° C. gives rise to hemipeptone.
Digested with pepsin in insufficient quantity, or with H_2SO_4 at 100° C. forms Antialbuminate (Meissner's parapeptone). Antialbuminate further digested with pepsin remains unchanged, but if digested with trypsin yields antipeptone.
Digested with trypsin, for however long a period, yields antipeptone.
Acted on by pepsin, remains unchanged.
Digested with trypsin, or H_2SO_4 at 100° C., gives rise to leucin, tyrosin, &c.

It must not be supposed that the whole of the albuminous compounds introduced into the stomach under ordinary circumstances are converted into peptone. Some forms of albumin, as white of egg, undergo, in part, direct absorption, whilst a part is absorbed as soon as it is converted into syntonin (Brücke). This action of the gastric solvent upon the azotized constituents of the food is dependent upon several accessory conditions. One of the most important of these is *temperature*. A heat of from 96° to 100° is required to keep up the solvent process, which is retarded according to the depression of the thermometer below this standard; so that at the ordinary temperature of the atmosphere it is completely suspended, to be renewed, however, with an increment of heat. On the other hand, a trifling elevation of temperature above 100° F. occasions a decompositon in the gastric juice, which entirely destroys its solvent power. The next condition, which specially affects the time required for the process of solution, is *motion*. This does not act mechanically, by way of "trituration," as was once supposed; for food is found to be digested, when enclosed in metallic balls perforated to admit the

access of gastric juice to their interior. But it answers the purpose of thoroughly subjecting the whole of the alimentary bolus to the agency of the gastric solvent, by bringing each part successively into contact with the lining membrane of the stomach, from the surface of which the fluid is effused. The *removal of the matters already reduced or dissolved*, also, has a most important effect in facilitating the solution of the remainder. This removal is due in part to the absorption of the matters in a state of solution, into the blood-vessels of the walls of the stomach; and in part to the successive escape of the reduced portions through the pyloric orifice. The importance of the previous state of *minute division* and *incorporation with aqueous fluid*, in promoting the action of the gastric solvent, has been already dwelt on (§ 101). The presence of either trypsin, bile or strong acids, or of alcohol, altogether arrests the solvent action of the gastric juice. A concentrated saline solution, or the employment of any mechanical means which prevent the swelling of albuminous substances materially interferes with gastric digestion. Gelatin and gelatin-yielding tissues, like tendon, fibrous tissue and skin, are only slowly acted on by the gastric juice, the fluid resulting from their solution retaining for some time its power of solidifying; ultimately, however, a syrupy fluid results, which will not gelatinize, and which will dialyze to some extent.* The solvent power of the gastric juice in the living body is difficult to determine, since it differs with the animal and with the nature of the food. The gastric juice of Carnivora is the most active, then that of Herbivora, whilst that of man appears to be comparatively feeble; and in this point, therefore, he appears to be most closely allied to the Herbivora. About 20 ozs. of the gastric juice of the dog are required to dissolve 1 oz. of coagulated albumin.† The strongly acid gastric juice of the Carnivora appears to be best adapted for the solution of animal albumin, whilst the weakly acid gastric juice of the Herbivora is far more efficacious in dissolving vegetable albumin or glutin.‡ In experiments with artificial gastric juice, Brücke§ found that at a temperature of 65° F., the most active fluid for raw fibrin contained 12½ to 15 grains of muriatic acid in one litre (1·76 pints), whilst the most active fluid for albumen, coagulated by heat, contained from 18·5 to 24·7 grains of this acid in the litre.

114. The presence of a *special ferment*, capable of *converting starch into sugar* in the fluids secreted by the stomach, is shown by the experiments of Dr. Smith on Alexis St. Martin, evidence of the presence of grape-sugar having been found an hour and a half after bread and water had been introduced through the fistulous orifice, the man carefully avoiding to swallow his saliva during that period. Under ordinary circumstances the conversion of starch into sugar is effected by the continuance of the action of the saliva with which the food has been impregnated in the mouth, or which has been subsequently swallowed. The action has been found to be materially checked when, by tying the œsophagus, the entrance of saliva into the stomach is prevented.‖ It has been noticed by Hoppe-Seyler, that when large quantities of cane-sugar are taken, a condition of gastric catarrh, attended with the secretion of much mucus, is induced, and that the cane-sugar then undergoes, probably in consequence of its rapid transformation into grape-sugar, speedy absorption. Oleaginous substances appear to be merely liquefied and finely

* See Henle and Meissner's "Bericht," 1860, p. 269; and Henle and Pfeuff's "Zeitschrift," Band xiv. 1863, p. 303; Mohlenfeld, Pflüger's "Archiv," 1872, Band v. p. 381; v. Wittich, idem., p. 435. † Lehmann and Corvisart.

‡ Koopman's "Nederland. Lancet," t. v. 1856. § Op. cit. p. 300.

‖ Brucke, "Vorlesungen über Physiologie," 1874, p. 300.

divided, in which state they are diffused through the pulpy chyme.* The decomposition of the fats into fatty acids and glycerin, sometimes commences in the stomach, as is indicated by the presence of the butyric acid which has been so frequently observed. The horny tissues of animals, as the nails, hair, and epidermis, elastic tissue, and mucin, are but slightly, if at all, acted on by the gastric juice.

115. It is only when either alimentary or some other substances capable of exciting irritation are present in the stomach, that the gastric juice is poured forth. So long as it is empty, the secretion which moistens its walls is neutral or even alkaline; but as soon as food is taken, acid is poured forth, and this in increasing quantities, until a certain time after the commencement of the digestive process, when the acidity of the stomach is at its maximum. In proportion as the alimentary matter is dissolved, however, and is either at once absorbed, or escapes through the pyloric orifice, the acidity of the stomach diminishes; and as soon as its cavity is emptied, the secretion of its walls is neutral again.† The circumstance that the stomach does not itself undergo digestion, even when that process is being actively performed on its contents, is of considerable interest, and must be attributed to the saturation of the whole mucous membrane with blood containing a large proportion of alkaline salts, for it has been shown by Dr. Pavy, that if one or two vessels of the stomach be tied, the parts thus deprived of the circulatiou of the blood are killed and then undergo the ordinary process of digestion, perforating ulcers occuring precisely analogous to those described by Hunter as seen in the bodies of men killed by accident during the digestion of a full meal. It must be remembered, also, that the pepsin present in the glands of the stomach is inoperative till it has mingled with the acid secreted on the surface. The mere fact of the part presented to the action of the gastric juice being alive does not prevent digestion from taking place, for if a snail, or slug, the leg of a frog, or the ear of a rabbit, be introduced through a fistulous opening into the stomach of a dog, signs of digestion are soon apparent.‡ The solvent action of the gastric juice has suggested its use as a remedial agent in old sores and fistulæ.

116. A very important series of observations on the conditions under which the gastric juice is secreted was made some years since by Dr. Beaumont, in the remarkable case of Alexis St. Martin, already several times referred to.§ "The inner coat of the stomach (as seen through the fistulous orifice), in its natural and healthy state, is of a light or pale pink colour, varying in its hues according to its full or empty state. It is of a soft or velvet-like appearance, and is constantly covered with a very thin, transparent viscid mucus, lining the whole interior of the organ. By applying aliment or other irritants to the internal coat of the stomach, and observing the effect through a magnifying glass, innumerable lucid points, and very fine papillæ can be seen arising from the villous membrane, and protruding through the mucous coat, from which distils a pure, limpid, colourless, slightly viscid fluid." (The papillæ here described appear to be the orifices of the gastric follicles, which are usually closed by their epithelial cells during fasting, and which would seem to become prominent when the *vis a tergo* of the secreted

fluid first causes this plug of cells to be cast forth.) "The fluid thus excited is invariably distinctly acid. The mucus of the stomach is less fluid, more viscid or albuminous, semi-opaque, sometimes a little saltish, and does not possess the slightest character of acidity. The gastric fluid never appears to be accumulated in the cavity of the stomach while fasting; and is seldom, if ever, discharged from its proper secerning vessels, except when excited by the natural stimulus of aliment, mechanical irritation of tubes, or other excitants. When aliment is received, the juice is given out in exact proportion to its requirements for solution, except when more food has been taken than is necessary for the wants of the system." The observations of Dr. Beaumont have been confirmed by those of M. Blondlot* and of M. Cl. Bernard,† which were made upon dogs in whose stomachs fistulous openings were maintained for a length of time. They found that the flow of gastric fluid is more excited by pepper, salt, and soluble stimulants, than it is by mechanical irritation; and that if mechanical irritation be carried beyond certain limits, so as to produce pain, the secretion, instead of being more abundant, diminishes or ceases entirely; whilst a ropy mucus is poured-out instead, and the movements of the stomach are considerably increased. The animal at the same time appears ill-at-ease, is agitated, has nausea, and, if the irritation be continued, actual vomiting; and bile has been observed to flow into the stomach, and escape by the fistulous opening. Similar disorders of the functions of the stomach result from violent pain in other parts of the body; the process of digestion in such cases being suspended, and sometimes vomiting excited. When acidulated substances, as food rendered acid by the addition of a little vinegar, were introduced into the stomach, the quantity of gastric fluid poured-out was much smaller, and the digestive process consequently slower, than when similar food, rendered alkaline by a weak solution of carbonate of soda, was introduced. If, however, instead of a weak solution, carbonate of soda in crystal or in powder was introduced into the stomach, a large quantity of mucus and bile, instead of gastric fluid, flowed into the stomach, and vomiting and purging very often followed. When very cold water, or small pieces of ice, were introduced into the stomach, the mucous membrane was at first rendered very pallid; but soon a kind of reaction followed, the membrane became turgid with blood, and a large quantity of gastric fluid was secreted. If, however, too much ice was employed, the animal appeared ill, and shivered; and digestion, instead of being rendered more active, was retarded. Moderate heat, applied to the mucus surface of the stomach, appeared to have no particular action on digestion; but a high degree of heat produced most serious consequences. Thus, the introduction of a little boiling water threw the animal at once into a kind of adynamic state, which was followed by death in three or four hours; the mucous membrane of the stomach was found red and swollen, whilst an abundant exudation of blackish blood had taken place into the cavity of the organ. Similar injurious effects resulted, in a greater or less degree, from the introduction of other irritants, such as nitrate of silver or ammonia; the digestive functions being at once abolished, and the mucous surface of the organ rendered highly sensitive. Amongst the most active stimulants of the gastric secretion is the saliva.

117. That the quantity of the Gastric Juice secreted from the walls of the stomach depends rather upon the general requirements of the system than upon the quantity of food introduced into the digestive cavity, is a principle of the highest practical importance, and cannot be too steadily kept

in view in Dietetics. A *definite proportion* only of aliment can be perfectly digested in a given quantity of the fluid, unless the products of the action of the juice are removed, in which case the action of the pepsin may be regarded as continuous, the action of which, like other chemical operations, ceases after having been exercised on a fixed and definite amount of matter. The cessation of the action is due, however, not to the pepsin losing its solvent power, since a comparatively *minute proportion, as in the case of other ferments, will convert an almost indefinite quantity of albumin or fibrin into peptone*, but rather to the presence of a great excess of the dissolved peptone interfering with further action, just as the presence of alcohol or lactic acid in large quantity interferes with those processes of fermentation in which these substances are respectively formed; in accordance with this, it is found that when the gastric juice is saturated with peptone and ceases to digest, the addition of a little diluted acid will immediately enable it to effect the conversion of a fresh portion of albumen.* Nevertheless, the statement of Dr. Beaumont is perfectly true as regards the living subject, that "When the juice has become saturated, it refuses to dissolve more; and, if an excess of food has been taken, the residue remains in the stomach, or passes into the bowels in a crude state, and becomes a source of nervous irritation, pain and disease, for a long time." The unfavourable effect of an undue burthen of food upon the Stomach itself interferes with its healthy action; and thus the quantity really appropriate is not dissolved. The febrile disturbance is thus increased; and the mucous membrane of the stomach exhibits evident indications of its morbid condition. The description of these indications given by Dr. Beaumont, is peculiarly graphic, as well as hygienically important. "In disease or partial derangement of the healthy function, the mucous membrane presents various and essentially different appearances. In febrile conditions of the system, occasioned by whatever cause—obstructed perspiration, undue excitement by stimulating liquors, overloading the stomach with food, fear, anger, or whatever depresses or disturbs the nervous system—the villous coat becomes sometimes red and dry, at other times pale and moist, and loses its smooth and healthy appearance; the secretions become vitiated, greatly diminished, or even suppressed; the coat of mucus scarcely perceptible, the follicles flat and flaccid, with secretions insufficient to prevent the papillæ from irritation. There are sometimes found, on the internal coat of the stomach, eruptions of deep-red pimples, not numerous, but distributed here and there upon the villous membrane, rising above the surface of the mucous coat. These are at first sharp-pointed and red, but frequently become filled with white purulent matter. At other times irregular circumscribed red patches, varying in size and extent from half an inch to an inch and a half in circumference are found on the internal coat. These appear to be the effects of congestion in the minute blood-vessels of the stomach. There are also seen at times small aphthous crusts in connection with these red patches. Abrasion of the lining membrane, like the rolling-up of the mucous coat into small shreds or strings, leaving the papillæ bare for an indefinite space, is not an uncommon appearance. These diseased appearances when very slight do not always affect essentially the gastric apparatus. When considerable, and particularly when there are corresponding symptoms of disease—as dryness of

* In a paper on this subject ("Cenno sulle Ricerche fatte del Prof. Schiff," &c., abstract in "Centralblatt," 1872, p. 788), Schiff states that the stomach of a healthy dog in good physiological condition requires 200 litres (about 44 gallons) of water to develope its full digestive power, and the infusion of the stomach of a large dog in this quantity of water will digest 162 lbs. of albumen! Bennett ("Text Book of Physiology," 1872, p. 203) observes that one part of pepsin dissolved in 60,000 parts of water still possesses a distinct digestive action. See also Arthur Ransome, "Journ. of Anat. and Phys.," 1875-6, vol. 10, p. 459

the mouth, thirst, accelerated pulse, &c.—*no gastric juice can be extracted by the alimentary stimulus.* Drinks are immediately absorbed or otherwise disposed of; but food taken in this condition of the stomach remains undigested for twenty-four or forty-eight hours, or more, increasing the derangement of the alimentary canal, and aggravating the general symptoms of disease. After excessive eating or drinking, chymification is retarded; and, though the appetite be not always impaired at first, the fluids become acrid and sharp, excoriating the edges of the aperture, and almost invariably producing aphthous patches and the other indications of a diseased state of the internal membrane. Vitiated bile is also found in the stomach under these circumstances, and flocculi of mucus are more abundant than in health. Whenever this morbid condition of the stomach occurs, with the usual accompanying symptoms of disease, there is generally a corresponding appearance of the tongue. When a healthy state of the stomach is restored, the tongue invariably becomes clean.* According to the experiments of Dr. Severé,† the process of alcoholic fermentation is materially interfered with by fresh gastric juice, the obstructing agency being exerted upon the ferment, and not upon the fermentable substance. The lactic acid fermentation is not checked by fresh gastric juice; but this fluid, as Spallanzani long ago showed, is capable of completely stopping the progress of putrefactive fermentation. The Temperature of the stomach rises with the increase of vascular and secretory activity which takes place during digestion. Dr. F. Smith found the ordinary temperature of St. Martin's stomach while fasting to be 98°-99° Fahr., whilst during digestion it rose to 100°-101° Fahr.‡

118. That the secretion of Gastric Juice is affected in a very marked manner by conditions of the Nervous system is indicated by the effect of mental emotions in putting an immediate stop to the digestive process, when it is going-on with full vigour. It does not appear to be exactly determined by what channel such influence is conveyed. Experiments which have been made upon animals with a view of ascertaining the share which the nervous influence conveyed by the *Pneumogastrics* takes in digestion, have led to different, though perhaps when all the conditions are considered, to reconcilable results in the hands of different experimenters. The *immediate* result of the division of these nerves is to arrest the movements and the secretion of the stomach. The organ becomes pale and flaccid,§ the reaction of the juice feebly acid or neutral, and the quantity of pepsin produced diminished.‖ Any food that

* Dr. A. Combe's commentary on the above passage is too apposite to be omitted. "Many persons who obviously live too freely, protest against the fact, because they feel no immediate inconvenience, either from the quantity of food, or the stimulants in which they habitually indulge; or, in other words, because they experience no pain, sickness, or headache,—nothing, perhaps, except slight fulness and oppression, which soon go off. Observation extended over a sufficient length of time, however, shows that the conclusion drawn is entirely fallacious, and that the real amount of injury is not felt at the moment, merely because, for a wise purpose, Nature has deprived us of any consciousness of either the existence or the state of the stomach during health. In accordance with this, Dr. Beaumont's experiments prove, that extensive erythematic inflammation of the mucous coat of the stomach was of frequent occurrence in St. Martin after excesses in eating, and especially in drinking, even when no marked general symptom was present to indicate its existence. Occasionally, febrile heat, nausea, headache, and thirst were complained of, but not always. Had St. Martin's stomach, and its inflamed patches, not been visible to the eye, he too might have pleaded that his temporary excesses did him no harm; but, when they presented themselves in such legible characters that Dr. Beaumont could not miss seeing them, argument and supposition were at an end, and the broad fact could not be denied."

‖ Schiff, Op. cit., Leçon xxxii.

nay be contained in it consequently undergoes only slight and superficial ligestion. If the animal survives the respiratory and circulatory troubles resulting from the operation, a reëstablishment of the digestive power manifests tself after an interval of some days; and the experiments of both Dr. Reid* and Schiff show that when life is sufficiently prolonged, the power of assimiation and absorption is almost completely restored: the evidence of this restoration consisting in the recovery of flesh and blood by the animals, the acidity of the contents of the stomach, and the disappearance of a considerable quantity of alimentary matter from the intestinal canal, with the existence of chyle in the lacteals.† Longet‡ found that milk was coagulated on the second day after the division of the pneumogastrics, and that *small quantities* of meat or other food were digested easily enough, though large masses were only superficially affected. The experiments of Schiff§ seem to prove that the chief *permanent* effect of section of the pneumogastrics is to prevent the stomach from coöperating in the act of vomiting, whilst it does not interfere with the reflex movements of digestion. Both Budge and Schiff maintain that these nerves are the conductors by which *sensory* and *painful impressions* affecting the stomach are conveyed to the mind. The inquiries which have been made in reference to the action of the *Sympathetic* upon the secretion of the gastric juice are, owing to the difficulties which attend experiments upon this point, comparatively few. Budge extirpated the cœliac and meseraic ganglia, and also divided the pneumogastrics, and still found (with one exception) that after the lapse of nine hours the stomach gave an acid reaction; and his results were fully corroborated by Ravitsch,‖ who found that section of the vagi at the œsophageal opening, involving section of the sympathetic, had little or no influence upon either the secretion of the gastric juice or the absorption of the chyme, though the latter was somewhat prolonged: and by Schiff, who divided the splanchnic nerves without effect. Adrian** only obtained negative results as regards the gastric secretion after extirpation of the Cœliac Plexus, which he must have accomplished with great dexterity, as the animals lived for months after the operation.†† The influence exerted by these nerves is probably due to their action on the vessels. Stimulation of the splanchnic nerves induces pallor of the mucous membrane.

119. There can no longer be any doubt that the operation of *Gastric Digestion* is one essentially of *chemical solution;* and that the *vital* attributes of the Stomach are only exercised in the preparation of the solvent, and in the performance of those movements which promote its action on the alimentary matters submitted to it. The first series of facts which clearly demonstrated this position were those that resulted from the very painstaking observations made by Dr. Beaumont in the case of St. Martin already referred-to. By introducing a tube of india-rubber into the empty Stomach, Dr. Beaumont was able to obtain a supply of gastric juice whenever he desired it, the tube serving the purpose of stimulating the follicles to pour forth their secretion, and at the same time conveying it away; and with the fluid thus obtained,

* "Edinb. Med. and Surg. Journ.," April, 1839; and "Physiological, Anatomical, and Pathological Researches," chap. v.—Dr. Reid's results have been confirmed as to this important particular by Hübbenet (Op. cit.) and by Bidder and Schmidt, "Ill. Med. Zeitung," 1852, Heft viii. p. 112.

†† Bernard, however, states ("Med. Times and Gazette," 1860, vol. ii.) that on galvanizing the sympathetic nerves distributed to the stomach, a sudden arrest of the secretion occurred.

he was able to make various experiments, which showed that the change which it effects upon alimentary matter, when it is kept at a temperature of 98° or 100°, and frequently agitated, is not less complete than that which takes place when the same mattter is submitted to its operation within the stomach, but requires a longer time. This is readily accounted-for when we remember that no ordinary agitation can produce the same effect as the curious movements of the stomach; and that the continual removal, from its cavity, of the matter which has been already dissolved, must aid the operation of the solvent on the remainder. The following is one out of many experiments detailed by Dr. Beaumont:—"At 11½ o'clock A.M., after having the lad fasting for 17 hours, I introduced a gum-elastic tube, and drew off an ounce of pure gastric liquor, unmixed with any other matter, except a small proportion of mucus, into a three-ounce vial. I then took a solid piece of boiled recently-salted beef, weighing three drachms, and put it into the liquor in the vial; corked the vial tight, and placed it in a saucepan filled with water, raised to the temperature of 100°, and kept at that point on a nicely-regulated sand-bath. In *forty* minutes digestion had distinctly commenced over the surface of the meat. In *fifty* minutes, the fluid had become quite opaque and cloudy; the external texture began to separate and become loose. In *sixty* minutes, chyme began to form. At 1 o'clock P.M. (digestion having progressed with the same regularity as in the last half-hour), the cellular texture seemed to be entirely destroyed, leaving the muscular fibres loose and unconnected, floating about in fine small shreds, very tender and soft. At 3 o'clock, the muscular fibres had diminished one-half since the last examination. At 5 o'clock, they were nearly all digested; a few fibres only remaining. At 7 o'clock, the muscular texture was completely broken down, and only a few of the small fibres could be seen floating in the fluid. At 9 o'clock, every part of the meat was completely digested. The gastric juice, when taken from the stomach, was as clear and transparent as water. The mixture in the vial was now about the colour of whey. After standing at rest a few minutes, a fine sediment of the colour of the meat subsided to the bottom of the vial.—A piece of beef, exactly similar to that placed in the vial, was introduced into the stomach, through the aperture, at the same time. At 12 o'clock, it was withdrawn, and found to be as little affected by digestion as that in the vial; there was little or no difference in their appearance. It was returned to the stomach; and, on the string being drawn out at 1 o'clock P.M., the meat was found to be all completely digested and gone. The effect of the gastric juice on the piece of meat suspended in the stomach was exactly similar to that in the vial, only more rapid after the first half-hour, and sooner completed. Digestion commenced on, and was confined to, the surface entirely in both situations. Agitation accelerated the solution in the vial, by removing the coat that was digested on the surface, enveloping the remainder of the meat in the gastric fluid, and giving this fluid access to the undigested portions."* Many variations were made in other experiments; some of which strikingly displayed the effects of thorough mastication, in aiding both natural and artificial digestion.

120. The attempt was made by Dr. Beaumont to determine the relative digestibility of different articles of diet, by observing the length of time requisite for their solution.† But, as he himself points-out, the rapidity of

* Experiments 2 and 3 of First Series.

† It is important to bear in mind that the digestibility of different substances bears no relation to their nutrient value, which is entirely dependent on their chemical composition. Of course, however nutritious a substance may be, it is valueless as an article of diet if it

digestion varies so greatly, according to the quantity eaten, the nature and amount of the previous exercise, the interval since the preceding meal, the state of health, the condition of the mind, and the nature of the weather, that a much more extended inquiry would be necessary to arrive at results to be depended-on. Some important inferences of a general character, however, may be drawn from his researches.—It seems to be a general rule, that the flesh of wild animals is more easy of digestion than that of the domesticated races which approach them most nearly. This may, perhaps, be partly attributed to the small quantity of fatty matter that is mixed-up with the flesh of the former, whilst that of the latter is largely pervaded by it. For it appears from Dr. Beaumont's experiments that the presence in the stomach of any substance which is difficult of digestion interferes with the solution of food that would otherwise be soon reduced. It seems that, on the whole, Beef is more speedily reduced than Mutton, and Mutton sooner than either Veal or Pork. Fowls are far from possessing the digestibility that is ordinarily imputed to them; but Turkey is, of all kinds of flesh except Venison, the most soluble. Perhaps the average period required for the digestion of an ordinary meal, and the complete emptying of the stomach, may be roughly estimated at from 3 to 4½ hours.—Dr. Beaumont's experiments further show that *bulk* is as necessary for healthy digestion, as the presence of the nutrient principle itself. This fact has been long known by experience to uncivilized nations. The Kamschatdales, for example, are in the habit of mixing earth or saw-dust with the train-oil on which alone they are frequently reduced to live. The Veddahs, or wild hunters of Ceylon, on the same principle, mingle the pounded fibres of soft and decayed wood with the honey on which they feed when meat is not to be had; and on one of them being asked the reason of the practice, he replied, "I cannot tell you, but I know that the belly must be filled." It is further shown by Dr. Beaumont that soups and fluid diet are not more readily chymified than solid aliment, and are not alone fit for the support of the system; and this, also, is conformable to the well-known results of experience; for a dyspeptic patient will frequently reject chicken-broth, when he can retain solid food or a richer soup.—Dr. Beaumont also ascertained, that moderate exercise facilitates digestion, though severe and fatiguing exercise retards it. If even moderate exercise be taken *immediately* after a *full* meal, however, it is probably rather injurious than beneficial; but if an hour be permitted to elapse, or if the quantity of food taken have been small, it is of decided benefit. The influence of temperature on the process of solution is remarkably shown in some of Dr. Beaumont's experiments. He found that the gastric juice had scarcely any influence on the food submitted to it, when the bottle was exposed to the cold air, instead of being kept at a temperature of 100°. He observed, on one occasion, that the injection of a single gill of water at 50° into the stomach sufficed to lower its temperature upwards of 30° degrees; and that its natural heat was not restored for more than half an hour. Hence the practice of eating ice after dinner, or even of drinking largely of cold fluids, is very prejudicial to digestion.—Dr. Marcet* suggested, and his suggestion has been adopted with good results, that in cases where the digestive powers are feeble the process of digestion should be carried on to some extent prior to its introduction into the stomach, and for this purpose recommends that to 1 lb. of roast meat finely minced,

cannot be dissolved; but, on the other hand, substances which are very easily digested (such as farinaceous matters) may have a low nutritive value, through containing but a very small proportion of azotized constituents.

* "A New Process for Preparing Meat for Weak Stomachs," 1867.

10 ozs. of a weak solution of hydrochloric acid (containing 232 grains of th pure acid, sp. gr. 1·1496, to one pint of water), 10 ozs. of water and 15 grain of pepsin should be added; the whole being kept for three hours in a ston jar immersed in boiling water. The meat is thus reduced to a pulp, whic will keep for a day or two. When required for use 51 grains of dry Sodiun Carbonate, or 81 grains of crystallized Sodium Bicarbonate must be added It is far from being true, however, that (according to the older view of its power) the Gastric juice is capable of acting upon *all* the nutritive com ponents of the food. The mistake probably arose from the *reduction* to whic these matters are subjected in digestion, the alimentary bolus being completely disintegrated, and its particles saturated with the fluids of the stomach, so tha the whole forms a homogeneous liquid of pultaceous consistence, to whic the name of *chyme* is given. This chyme will, of course, vary greatly in its composition, according to the proportion of the different alimentary substances that have entered into the composition of the food; and its appearance, also, is far from uniform, being sometimes like gruel, but sometimes more creamy, always, however, having a strong acid reaction.

121. Although the *Chyme*, or product of gastric digestion, which escapes through the pyloric orifice into the duodenum, contains much azotized matter in a state of actual *solution*, a considerable proportion of it is still only *reduced* and mechanically *suspended;* and the solution of the latter is continued in the intestinal tube. In the farinaceous part of the food, moreover, no great amount of change has hitherto been effected; and the sugar which has been generated by the agency of the salivary ferment is probably absorbed into the blood-vessels nearly as fast as it is formed. In the condition of the fatty matters no important change is perceptible, except such as results from the solution of the membranes, &c., that enclosed them. Hence we see that the process of Digestion, so far from being completed in the stomach, has only been carried one stage further;* but soon after its entrance into the Duodenum, the chyme is subjected to the actions of the Bile, the Pancreatic fluid, and the Intestinal juice or "Succus entericus" which is secreted by Brunner's glands and the Lieberkühnian follicles. Of these, the *Pancreatic* fluid will be first noticed.

122. In structure the Pancreas closely resembles the Salivary glands (§ 102), though its texture is looser, for it consists of racemose clusters of secreting follicles, so elongated as to be almost tubular, which form the terminations of the ramifying divisions of the duct: each cluster, with its blood-vessels, lymphatics, nerves, and connective tissue, forms a lobule; and the separate lobules are held together by areolar tissue, as well as by the vessels and ducts. The cells lining the acini are arranged in two layers, of which the outer or parietal is composed of slender columnar cells that are transparent, and stain deeply with carmine, whilst the inner or central cells are granular, and stain less deeply. Besides these, fusiform or branched cells are seen here and there in the middle of the acini, which have been named "centro-acinar cells." The processes of these cells penetrate to the wall of the acinus, between the secreting cells, and are believed to act as supporting bodies. Heidenhain† finds that in the fasting condition the granular internal layer of cells occupies the larger, and the homogeneous external layer the smaller part of each acinus. During the first period of digestion, when the liveliest secretion is taking

* During the digestion of vegetable food the Chyme, according to Cl. Bernard (V. Gorup-Besanez, "Phys. Chem.," 1874, p. 305) is alkaline, whilst during the digestion of animal food it is acid.

† Pflüger's "Archiv," Band x. 557.

place, all the cells diminish in size, owing to consumption of the granular internal zone, *with subsequent* increase of the external layer, so that these become enlarged. In the second period of digestion, during which secretion diminishes, and the gland becomes quiescent, new formation of the internal zone takes place at the cost of the homogeneous external zone, which becomes extremely attenuated, and both sets of cells enlarge. In inanition there is gradual increase of the cells to their original size, with slight diminution of the internal zone. Heidenhain thinks that in the living gland-cell in the first instance, not perfect Trypsin, but a mother substance which he terms Zymogen, is prepared, which is soluble in water, and after a time, under the influence of oxygen, sets free Trypsin. Zymogen is probably a combination of Trypsin with an albuminate. During active secretion the amount of Zymogen diminishes, whilst it is stored up again during the period of rest, being most abundant about the fourteenth hour. If the gland be injected from the duct of Wirsung a series of branching tubes is brought into view, which has led various observers* to believe that the secretory cells of the pancreas, like those of the liver, are surrounded by extremely fine ducts, which convey the secretion into the larger excretory passages; others, however, believe that there are no such independent tubes, the appearance being due to the injection forcing its way not only in the axis of the canal, but escaping into the spaces between adjoining cells. Like both the liver and the salivary glands, the *development* of the pancreas commences about the fourth week by the formation of a tubular process of the alimentary canal at a particular spot upon which a mass of cells has previously accumulated. The secretion of this gland resembles saliva in its general appearance, being clear and colourless, of saline taste, free from smell, alkaline in its reaction, owing to the presence of sodium carbonate, and very viscid. Upon the application of heat, or upon the addition of any of the stronger mineral acids, it evolves carbonic acid gas, and coagulates into a solid mass like the white of an egg. This appears to be due to the presence of alkali-albumin and serum-albumin, as well as to a peculiar form of albumin, which is precipitated in a gelatinous condition at a temperature of 32° F. from the concentrated secretion.† The properties of the secretion seem to vary according to the period of digestion at which it is collected, being at first very tenacious, and coagulating completely, and at a later period becoming thinner, more alkaline, and less perfectly coagulable by heat; its solvent powers upon various constituents of food are, at the same time, less strongly marked. Viscid pancreatic juice obtained from the duct contains 90° per cent of water, the remainder consisting of about 9 per cent. of organic substances and about 1 per cent. of ash, seven-tenths of which last is common salt.‡ When the secretion is profuse, the proportion of organic matter diminishes considerably.§ Leucin, Guanin, and Tyrosin, have been stated to be constant constituents of the substance of the gland, and Leucin and Xanthin have occasionally been found in the secretion. Recent experiments, however,‖ render it probable that these substances proceed from the action of the secretion on the albuminous constituents of the blood, or even on the tissue of the gland itself.

123. The nature of the organic substance which forms so large a part of the solid residue of the pancreatic juice, and which is so singularly prone to decomposition, has not been accurately determined. Bernard states that it resembles albumen in being precipitated by heat, acids, alcohol, and metallic salts, but differs in being thrown down by sulphate of magnesia, and by the circumstance that, after being precipitated by alcohol, it can be re-dissolved in water. The quantity of the secretion which is poured forth in twenty-four hours has been variously estimated; and perhaps the differences are due, as Bernard has suggested, to the circumstance that when the operation for the formation of a pancreatic fistula has been attended with much violence, when the gland has become inflamed, and the health of the animal has in consequence suffered, the fluid secreted is abnormal, and differs both in quantity and in many of its most essential properties, from the healthy secretion. From these considerations, and from the probably intermittent character of the secretory act, it is manifest that only an approximative estimate of the absolute quantity can be made. Bernard estimates the quantity secreted per hour in the dog, for every 1lb. weight of the animal, at about 15 grains; Schmidt and Kröger at from 20 to 35 grains;* Skrebitzky and Bidder at from 21 to 35 grains. If this last estimate were applied to man, it would give from 12 ozs. to 16 ozs. av. as the total quantity of pancreatic juice secreted per diem, and the pressure under which it is secreted appears to be about 17 mm. of mercury. Bernard describes the gland as pale and flaccid during the period of fasting, and as rosy, but not deep red, some time after food has been taken, when the secretion is rapidly poured forth. The activity of the gland seems to be greatest at the middle or towards the close of gastric digestion,† and at the period, therefore, of the passage of the contents of the stomach into the small intestine. Under the toxic influence of curare, the secretion is greatly augmented. The discharge of pancreatic juice commences as soon as food is introduced into the stomach, and is evidently, therefore, of a reflex nature. The afferent nerve is probably the pneumogastric, and the centre of reflexion is seated in the medulla oblongata, whilst the motor nerves‡ run first in the pneumogastric and splanchnic nerves, and afterwards in the hepatic, splenic, and superior mesenteric plexuses. The secretion may be excited by stimulation of the medulla oblongata, or by direct stimulation of the gland. It may be suppressed by atropin,§ by efforts to vomit, and by stimulation of the proximate stump of the divided pneumogastric, or of the sciatic and other sensory nerves.‖ Section of the nerves accompanying the vessels causes congestion of the gland and a profuse flow of watery secretion (paralytic secretion), which continues even when no food is given to the animal. The nerves terminate, according to Pflüger, in the same way as in the salivary glands, by penetrating the

* See M. Edwards, "Leç. sur. la Physiol.," 1860, p. 522. Colin obtained about 10 ozs. per hour from a cow of medium size and from a horse, but only 3 drachms from a pig.

† Weinmann observed in a dog during the first hour after a full meal 1510 grains secreted whilst after a 45 hours' fast only 7½ grains (Henle and Pfeuffer's "Zeitschrift," N. F. Band iii. p. 247). Kröger obtained 384 grains during the 1st hour, 271 in the 2nd, 225 in the 3rd, 4th, 5th, and 6th, 176 in the 7th, 8th, and 9th, 165 from the 10th to the 14th, and 103 from the 19th to the 24th ("Archiv. Gén. de Méd.," i. 1861, p. 533). Bernstein ("Leipziger Arbeiten," 1870, p. 6) obtained scarcely any from fasting dogs, but remarked a considerable increase (0·6—2·2 cc. in 10 min.) during the 1st hour after feeding, the quantity attaining its maximum at the 2nd or 3rd hour (about 5 cc. in 10 min.), then diminishing to the 5th hour, when a slight increase took place till the 7th hour, after which it gradually fell to zero.

‡ See Afanassiew and Pawlow, Pflüger's "Archiv," Band xvi., 1878, p. 173, and Band xvii. p. 555.

§ Pawlow found this effect in dogs, but not in cats. Ibid., 1878, Band xvii. p. 557.

‖ See Bernstein, Ludwig's "Arbeiten," 1870, p. 1.

secreting cells. It would seem, then, that the gland receives sensory or afferent; motor, secretory, or efferent; and inhibitory nerves; and the general relations of the gland to the nervous system are essentially similar to those of the salivary glands. As the organ is of considerable size, is very constant amongst the Vertebrata, and uniformly discharges its secretion into the duodenum, it is natural to suppose that it must exert an important influence in preparing the food for absorption; and this is fully borne out by our knowledge of the serious interference to the due performance of this function, which results from disease of the pancreas, and of the extreme instability of the organic matter contained in its secretion.

124. It has been already pointed out (p. 69) that three separate hydrolytic ferments are found in the pancreas and the fluid it secretes—*Amylopsin*, which, like diastase, is capable of converting starch into dextrin and a peculiar form of sugar; *Myopsin*, or *Trypsin*, which, like pepsin, can convert the albuminous compounds into peptones; and *Steapsin*, which has the power of breaking up fats, if water be present, into glycerin and the corresponding fatty acids. The amylolytic power* of the pancreatic juice, which resembles, but is much more active than that of saliva, was first observed by Valentin, and may be proved by adding the secretion obtained from a fistulous opening into the duct, or even an infusion of the gland-substance, to either crude or boiled starch; for though the energy of the action is much greater on starch paste, yet even in the case of the raw material, the starch-grains become rapidly altered in form, disintegrated, and dissolved, reducing dextrins, maltose and glucose being successively produced.† The necessity which exists for the conversion of starch into sugar before it can be absorbed renders evident the advantage which attends the presence of a gland possessing a similar transforming power to that of saliva, at some distance from the mouth, where it may act upon crude starch which has been softened, swollen, and otherwise affected by the combined heat and moisture of the stomach. Cane-sugar and Inulin are unaffected by it. Its operation on starch is not interfered with by the presence of the gastric juice, or of the bile. The amylolytic ferment does not appear to be present in the pancreas of the new-born child.‡ Glycogen is acted on much more slowly than starch-paste.

125. The action of the pancreatic juice upon the fats, first demonstrated by Cl. Bernard, is of a double nature. In the first place, it forms with great rapidity, when agitated with them, a remarkably persistent emulsion, and, secondly, it effects their decomposition, providing water be present, into glycerin and the fatty acids. Its action upon Lecithin, a substance that may be regarded as one of the steps in the formation of fats, is the same as on the neutral fats,§ the products being glycerin-phosphoric acid, neurin, and fatty acids. Several hours are required for the process of disintegration, both in the case of fats and of Lecithin, at a temperature of about 100° F.,

* The term "amylolytic," meaning the power of converting starch into sugar, was first employed by M. Foster (Humphry and Turner's "Journal of Anat. and Physiol.," vol. 1866, p. 108). For an attempt to determine the composition of pancreatic ferment, see Liversidge and Clowes, "Journ. of Anat. and Phys.," vol. viii. p. 25.

† In unhealthy conditions of the body it is not unlikely that the same changes may take place in the system as occur when pancreatic juice is allowed to remain long in contact with starch-paste at a moderately high temperature; these changes being accompanied with the evolution of hydrogen, nitrogen, and carbonic acids, indicating the occurrence of the lactic, butyric, or even alcoholic fermentation. See Musculus and de Mering, "Acad. d. Sciences," Jan. 13, 1879.

§ Bokay, "Zeits. f. Phys. Chemie." Band i, 1877, p. 163.

and hence it may to some extent be a putrefactive process.* That this emulsifying action is exerted in the body is shown by the interesting researches of Bernard, who observed that in the Rabbit (in which animal the pancreatic duct discharges itself some inches lower down in the intestine than does the bile duct), when fatty matters have been introduced into the alimentary canal, no considerable change occurs until they have passed the orifice of the pancreatic duct; an oily emulsion being then for the first time apparent, and the opaque whiteness of chyle showing itself in the contents of those absorbents only which originate in the intestinal villi below that orifice. Bernard also pointed out that by putting a ligature round the pancreatic duct, the digestion of oleaginous matter is so completely prevented, that it is found unchanged in the lower part of the intestinal tube, and no opalescent chyle is found in the lacteals. This position is further strengthened by the fact ascertained by clinical observation,† that there is a close relation between disease of the pancreas, and the discharge of fatty matters per anum. Colin‡ (of Alfort), however, made some ingenious experiments, in which he determined the quantity of fat contained in the chyle of cows and other animals, both before and after ligature of the pancreatic duct, and after extirpation of the gland. He was unable to discover any remarkable difference in its composition. Similar experiments were made by Herbst, Schiff, and Donders, from which the conclusion may be fairly drawn, that though the pancreatic juice is of considerable importance in the emulsification of fatty bodies, yet that its action is not indispensably requisite for their absorption; and it is possible, either as Frerichs and Hübbenet state, that the Succus Entericus may possess an emulsifying power of considerable energy, and quite sufficient, in the absence of the pancreatic juice, to prepare a due amount of fat to supply the demands of nutrition; or, as M. Peyrani,§ Voit,‖ and Schiff¶ contend, that the bile is an important agent in the digestion of this class of alimentary substances. In Busch's case, already referred to, the digestive action of the fluid poured forth by the lower part of the Jejunum and Ileum upon fatty bodies introduced into them through the fistulous orifice, was exceedingly imperfect. Steapsin or the fat decomposing ferment exists in the pancreas of the new-born child. It is not soluble

* Brücke ("Wiener Sitzungsber." Band lxi. 1870, Abtheil. ii. p. 362) has shown that oil mingled with dilute albumen, with fresh ox-gall still containing mucus, or with a dilute solution of borax, or sodium-carbonate, is much more easily and completely emulsified if, instead of being perfectly pure, it is somewhat rancid—that is to say, has been partly converted into, or contaminated with, the fatty acids. Pure and neutral oil, shaken up with either of these fluids, forms relatively large drops which rapidly reunite, but if mingled with fatty acids it forms after the first agitation a white milk. It would appear that whilst sodium-carbonate has little action in emulsifying fat, yet if free acids be present, these combine with a part of the soda to form a soap, which effects the emulsification of the oil. The same fact can be shown in another way by adding a small quantity of a solution of soap to pure oil, when an emulsion can be quickly made; and J. Gad ("Archiv f. Anatomie u. Physiologie, His. and Braune," 1878, p. 183) has pointed out that the mere contact of rancid oil with an alkaline solution causes an emulsion to be gradually formed, the particles near the line of contact of the two fluids being thrown into violent rotatory movements, and the emulsion being of the finest possible character. The drops soon begin to exhibit peculiar movements, sending out processes which after giving off a white milk are again drawn in, some small droplets separating, and the original drop assuming again a round form. If these separated particles be collected and immersed in another fresh portion of soapy fluid no new movements are observed.

glycerin, but is precipitated when burnt magnesia is added to the pancreatic juice.

126. Lastly, as originally stated by Corvisart,* healthy pancreatic juice, or the infusion of a healthy pancreas, or even a solution of precipitated pancreatin in distilled water, possesses a distinctly solvent action on albuminous compounds, converting them into peptones without the supervention of any signs of putrefaction. This action so far differs from peptic digestion that whilst pepsin converts albuminous compounds at once into acid-albumin, myopsin converts them without any previous process of swelling up into globulin, and then into true peptones which appear to be identical with the peptones found in gastric digestion.† The previous action of hydrochloric acid does not facilitate, but, on the contrary, rather impedes the action of myopsin or trypsin. The presence of oxygen gas is not required for the formation of the globulin substance.‡ The action seems to be one of a corrosive nature, the albumin breaking up into flocculi, which gradually dissolve till the fluid only presents a slight degree of turbidity. Various agents that are fatal to the lower forms of organic life have little influence on the disintegrating process exerted upon albuminous compounds by myopsin, or perhaps only somewhat retard this action. Thus arsenious acid and its salts,§ ether, and salicylic acid, unless very concentrated,‖ interfere but little with it. Antipepton, Tyrosin, and Leucin are largely formed during the action of pancreatic juice on proteids, the two latter substances more rapidly than in peptic digestion, but Indol is a product of their putrefaction.¶ Asparaginic acid is one of the products of the digestion of fibrin and glutin,** and may be an intermediate stage between albumin and urea. Gelatin is rendered fluid and soluble and dissolved, but nuclein and hæmoglobin resist solution. It is noticeable that the substances just mentioned as resulting from the action of myopsin on albuminous compounds contain progressively smaller quantities of nitrogen; albumin containing 15·17 per cent. of its weight of nitrogen; leucin, 10·7; asparaginic acid, 10·5; and tyrosin, 7·74. The following experiment performed by Meissner demonstrates the action of the pancreatic juice in the living body:— The duodenum in a dog was thoroughly washed out with a stream of warm water, and surrounded by a ligature above and below the point of entrance of the large duct of the pancreas. By this proceeding the entrance of the secretion of the superior duct, and of the bile through the ductus communis choledochus, was excluded. And now, the animal having previously been kept fasting for fifteen hours, 34 grammes of hard-boiled white of egg were introduced into the loop of intestine confined between the ligatures, whilst 20 grammes were at the same time introduced into the stomach, to supply the ferment with which he believed it to be requisite that the pancreas should be charged. After the lapse of fifteen hours the duodenum was examined, when 150 grammes of neutral fluid were found quite free from any odour of putrefaction, with 4 grammes of undissolved albumen; 30 grammes of this substance had consequently been dissolved. All observers are agreed that the most active pancreatic juice is

obtained from an animal in full digestion, as it is only at that time that the gland is thoroughly charged with the pancreatic ferment that is capable of digesting albuminous compounds. In new-born animals, and in conditions of gastric disease in which the normal acid secretion in the stomach is interrupted, pancreatic digestion may take place in the stomach,* giving rise, as has been frequently observed, to fatty infiltration of the epithelial cells lining the stomach, and repletion of the gastric lymphatics with chyle. Hoppe-Seyler states that he has observed pancreatic digestion in the matters vomited by a patient with gastric disease, strong peptic digestion occurring as soon as they were acidified with hydrochloric acid. In the later stages of pancreatic digestion sugar disappears, and it is probable that bacteria are normally produced. In a remarkable and well-observed case of atrophy of the liver and pancreas described by Dr. J. A. Flés, a considerable quantity of fat and undigested muscular fibre was found to pass away in the fæces, but after the daily administration of a calf's pancreas nearly all the *fat* and a great proportion of the *muscular tissue* disappeared.†

127. The Duodenum receives not only the Pancreatic, but also the *Biliary* secretion; and from the constancy with which this fluid is poured into the upper part of the intestinal tube, or even into the stomach itself, in all animals which have any kind of hepatic apparatus, it seems a legitimate inference that this secretion is not purely excrementitious, but serves some important purpose in the digestive process. It is not easy, however, to state with precision what this purpose is. The results of many of the experiments which have been made to determine it are vitiated by the fact, that the pancreatic duct in most cases discharges itself into the intestinal tube at the same point with the hepatic, and has thus been frequently involved in operations performed upon it.—As the most important constituents of Bile, and the agency of the Liver as an assimilating and depurating organ, will be more appropriately considered elsewhere (CHAPS. VI. and XI.), we shall here limit ourselves to the consideration of what may be regarded as the best-established facts in regard to the uses of the biliary secretion in the digestive process.

128. When Bile is mingled with fresh or artificial gastric juice, a precipitate falls which partly consists of glycocholic acid,‡ partly of albumin rendered insoluble by the taurocholic acid, of mucin and the colouring matter of the Bile, and partly of pepsin, which attaches itself to the precipitate.§ Dr. Dalton,‖ however, states that Bile does not form a precipitate with gastric juice holding albuminose (peptones) in solution. These fluids are therefore not finally antagonistic to each other in the digestive process, though at first they produce a precipitate on admixture.¶ When its action is tested out of the body, by mingling it with the different constituents of food, it is found to exert a slight but distinct action in converting starch into sugar.** It therefore

contains a diastatic ferment. It has no action upon cane-sugar, until it has stood a considerable length of time; but then it converts it into lactic acid. This change it speedily exerts, as do many other animal substances, upon grape-sugar. It has no action on albuminous substances, even when acidulated. When mingled with neutral oils or fats it forms with them a finely granular emulsion, well adapted to penetrate into the interior of the body, through the channels that will be hereafter described in the walls of the intestine; but if added to the fatty acids the biliary salts are decomposed, the glycocholic and taurocholic acids are set free and the soda uniting with the fatty acids, forms easily soluble soaps, which last may again augment the emulsifying power of the undecomposed bile. Wistinghausen* and Hoffmann† have shown that the force requisite to effect the filtration of an oily substance through an animal membrane is much less when the membrane is moistened with an alkaline fluid, or with bile, than when it is moistened with pure water. Bile certainly possesses an *antiseptic* power, for M. Bernard found that when two similar pieces of meat had been immersed for three months, one in a bottle of gastric juice alone, and the other in a mixture of gastric juice and bile, a strong ammoniacal odour resulting from decomposition was emitted from the former, whilst the latter was pure and free from any smell whatever. The difference is even more marked if an infusion of pancreas be used instead of the gastric juice. And it was remarked by MM. Tiedemann and Gmelin (and also recently by Hoffmann), that when the bile was prevented from passing into the alimentary canal, the contents of the latter were more fœtid than usual. Moreover, it is found that the admixture of bile with fermenting substances checks the process of fermentation; and M. Bernard‡ has shown by ingeniously-contrived experiments, that this power is exerted also to some extent in the living body. Hence we can understand how the reflux of bile into the stomach should seriously interfere with the process of gastric digestion;§ and how, when there is a deficient secretion of bile or more food is swallowed than the bile provided for it can act upon, or the character of the biliary secretion itself has undergone any serious pervertion, there should be much more than the normal amount of putrefactive fermentation, as is indicated by an evolution of flatus, and very frequently by diarrhœa. Schiff‖ and Budge¶ have shown that the bile produces energetic, and indeed almost tetanic spasms of the muscles, both voluntary and involuntary, when applied either to the tissue itself or to the nerves supplying it. Its importance, therefore, in maintaining the *peristaltic action of the intestine* is probably considerable, whilst by exciting the involuntary muscular fibre-cells of the villi it very probably materially aids the movement of the chyle in the lacteals. Moreover, the presence of a proper quantity of bile in the intestine seems to promote the secreting action of the intestinal glandulæ: this appears from the tendency to constipation which is usually consequent upon deficiency of the secretion, and from the diarrhœa which proceeds from its excess; and is confirmed by the purgative properties which inspissated

ox-gall has been found to possess. The value of the bile in the preparation and absorption of fats in digestion is shown by the fact that animals in which a biliary fistula has been established so that the bile escapes without entering the alimentary canal become thin, fail to take up more than one-fifth or one-seventh of the usual amount of fat, have transparent chyle, and discharge fat with the fæces. They may, however, live for months or even years* if supplied with a sufficient amount of food, for the appetite is greatly increased.

129. The best evidence that has hitherto been obtained of the quantity of Bile daily poured into the alimentary canal of man has been afforded by patients suffering from fistula of the cystic, or of the common bile duct. In one of these cases which was under the observation of v. Wittich† the quantity discharged amounted to 22·2 c.c. per hour, or 532·8 cub. cent., which are equivalent to one pint, in 24 hours. In another case observed by Westphalen‡ a man weighing about 140 lbs. discharged almost exactly the same quantity (7703 grains = 1 lb. 703 gr. av., or about one pint) with but small variation daily for 10 days. Nasse and Plattner§ obtained from a dog 105 grains, and Stackmann 108 grains per diem, for every 1 lb. of body weight. Bidder and Schmidt, from experiments on a dog, estimated the quantity in man at $3\frac{1}{2}$ lbs. daily, but such experiments have been shown by the Edinburgh Committee of the British Medical Association to afford no reliable data for comparative estimates, since the size and weight of the animals have no relation to the amount of bile secreted. In one instance a large dog weighing 42 lbs. secreted on an average only 1036 grains daily, while a dog weighing 11 lbs. secreted 1857 grains daily.‖ Schiff¶ has shown that a much larger quantity of bile is discharged into the duodenum under normal conditions than can be collected from a biliary fistula, the reason being that the bile is reabsorbed with great rapidity and is again excreted, together with fresh bile, by the liver. This observation has been confirmed by Laffter,** under Heidenhain's direction, the evidence relied on being the injection of bile into the duodenum, when its quantity was observed to be increased, and the injection of coloured bile or rhubarb into the intestine, which reappeared in the course of a minute in that flowing from the canula. Wolf†† found that the amount of secretion in dogs was proportional to the size of the liver; that it was more active in small and young animals; that it was most abundant on mixed diet (rising with the quantity of meat); less on a diet of bread or rice, and least on a diet of fat; and that it was greater by day than by night. It is augmented after ingestion of water though it is then of poorer quality, and also after vegetable diet. The quantity secreted by Herbivora is much greater than by Carnivora.

* At the meeting of the French Academy, June 23, 1851, M. Blondlot gave the history, and an account of the post-mortem examination of a dog that had lived five years without the passage of any bile into the intestinal tube. †† "Centralblatt," 1869, p. 86.

Prof. Rutherford has found, in an extensive series of experiments, that the secretion of bile is increased in dogs by the administration of podophyllin, rhubarb, aloes, colchicum, enonymin, sanguinarin, iridin, ipecacuan, colocynth, jalap, sodium sulphate, potassium sulphate, sodium phosphate, Rochelle salt, nitro-hydrochloric acid, and corrosive sublimate. It is not increased to any material extent by croton oil, magnesium sulphate, sodium chloride, potassium bicarbonate, ammonium chloride or calomel, and as a rule severe purgation diminishes the flow of bile.* Wolf in Man and Arnold† in Dogs found that the activity of the liver attained its maximum an hour or two after food, Voit‡ two hours after, Kölliker and Müller between the 6th and 8th hours, Bidder and Schmidt§ about 10 or 12 hours after a full meal, and Dr. Austin Flint‖ from the 2nd to the 8th hour.—As Dr. Dalton has remarked, a distinction should be drawn between the time at which the largest quantity of bile is discharged into the intestine, and that at which the secretory activity of the liver is at its height. In his own experiments on a dog, which appear to have been conducted with much care, a considerable quantity of bile was discharged into the intestine soon after feeding, as is shown in the following Table:—¶

Time after feeding.	Quantity of fluid in 15 minutes.	Dry residue of the same.	Quantity of biliary matter.	Proportion of biliary matter to dry residue.
Immediately	640 grains.	33 grains.	10 grains.	·30
1 hour	1990 „	105 „	4 „	·03
3, 6, 9 hours	780, 750, 860 „	60, 73, 78 „	4, 3½, 4½ „	·07, ·05, ·06
12, 15 „	325, 347 „	23, 18 „	3¾, 4 „	·16, ·22
21, 24, 25 „	384, 163, 151 „	11, 9½, 5 „	1, 3¼, 3 „	·09, ·34, ·60

The secretion diminishes considerably when food is withheld for some time; the quantity poured-out after ten days' starvation being only about one-eighth of what it is when at its maximum. Still it is obvious, that although its rate is thus greatly influenced by the stage of the digestive process (which is the less to be wondered-at, when it is remembered that the secretion is formed from blood that is charged with newly-absorbed and imperfectly-assimilated matters), the excrementitious character of the secretion requires that its elimination shall be constantly going-on to a certain degree; but a receptacle is provided in Man, as in most others among the higher animals whose digestion is performed at intervals, for the storing-up of the fluid until it can be usefully employed in that process. The intestinal orifice of the ductus choledochus is closed by a sort of sphincter; and the fluid secreted during the intervals of digestion, not being propelled with a force sufficient to dilate this, flows back into the gall-bladder, which dilates to receive it. According to Friedländer and Barisch** the pressure under which bile is secreted is very low, not much exceeding the blood pressure, or about 200 mm. of water, or 16 mm. of mercury. The presence of food, and especially of the acid products of gastric digestion, in the duodenum seems to excite the walls of the gall-

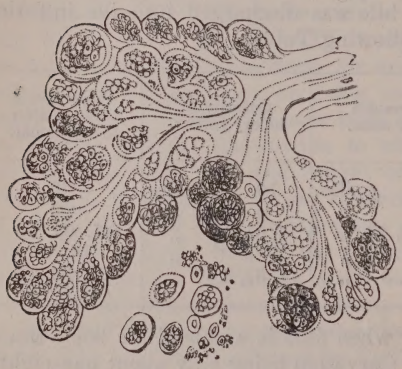
bladder and of the biliary ducts* (which contain a large quantity of non-striated muscular fibre), to a contraction sufficiently powerful to propel their contents into the intestine, in spite of the opposition of the sphincter; but whether this takes place through a reflex action of the nervous system, or through the direct stimulation of the muscular coat of the duct by the passage of alimentary matters over its orifice, we have at present no means of satisfactorily determining. It will be recollected that the gall-bladder is usually found distended with bile, in cases of death from starvation (§ 79), notwithstanding the diminution in the amount actually secreted. Of the bile which is poured into the intestinal tube, by far the greater proportion seems to be re-absorbed (§ 134), or at least to be so altered that the presence of the biliary acids can no longer be recognised.

130. Besides the biliary and pancreatic secretions, there is poured into the Intestinal canal a fluid secreted in its own walls, which has received the designation of *Succus Entericus*. The secretion of this fluid is partly the function of the Glands of Brünner, which are small, elongated racemose, or tubular glands† (Fig. 75), imbedded in the walls of the duodenum, and extending to the commencement of the jejunum, but chiefly of the follicles of Lieberkühn, with which the intestinal canal is furnished throughout its entire length. The cells lining Brünner's glands‡ are columnar in form, but destitute of a membrane, and have a lateral process at their attached extremity, near which the nucleus is situated. The nucleus is not apparent in fresh preparations. The cell-contents consist of proteids, mucin, a substance which is soluble in a 10 per-cent. solution of sodium chloride and is precipitable by alcohol, fat drops, and granules. The cells are small and cloudy in fasting, but large and bright during digestion. The secretion of the glands cannot be obtained separately during life, but when dissected out it is found that their watery extract converts starch into dextrin and sugar,§ dissolves fibrin, but not albumin at 35° C. (95° F.), and has no action on fats. Grützner‖ was unable to obtain any diastatic action with the extract, but found that it resembled pepsin in dissolving the proteids. The glands of Lieberkühn are

Fig. 75.



Portions of one of *Brünner's Glands*, from the Human Duodenum.

* Bernard and Küthe (Canstatt's "Jahresbericht," 1861, p. 131) found that touching the point of entrance of the biliary duct into the intestine with an alkaline fluid had little or no effect, whilst brushing it lightly over with an acid solution immediately caused a discharge of bile to take place.

† Puky Akos and Schlemmer ("Wien Akad. Sitzungsber.," 1869, Band lx. p. 31, and p. 169), and Renaut, "Soc. de Biol." Mars 8, 1879, regard these glands as belonging rather to the tubular than to the racemose type, whilst Schwalbe considers them to be intermediate to both. See Max Schultze's "Archiv," Band viii. p. 92. Toldt ("Mittheil. der ärtz. Vereins in Wien," Band i. p. 33) holds them to be racemose glands.

‡ According to Schwalbe, "Archiv f. Mic. Anat.," Band viii. p. 92, 1871.

§ Krolow, "Berl. Klin. Wochens.," 1870, No. 1

‖ Pflüger's "Archiv," Band xii. p. 228.

straight narrow cæca, standing side by side, with a little intervening adenoid substance (except where the Peyerian bodies lie amongst them), and corresponding in length with the thickness of the mucous membrane. They are lined by columnar epithelium. Their orifices are seen in the interspaces between the villi, where they are so closely set-together as to seem like the apertures of a sieve; and they are arranged in rings around the Peyerian glandulæ. Brünner's glands resemble the pancreas in structure. The cells become large and transparent during digestion. It has been found* that a glycerin extract of the glands when dissected out possesses both a peptic and a diastatic action, dissolving albumins and converting starch into sugar, but it had no action on fat. Costa found that glycerin extract of Brünner's glands, and of the Lieberkühnian follicles of the Horse possesses a diastatic action, but has no action on albumin or fat.

The *Intestinal juice*† appears to be a colourless viscid liquid, invariably alkaline in its reaction, and containing from 3 to $3\frac{1}{2}$ per cent. of solid matter. Its sp. gr. is about 1011. The total amount daily secreted in Man has been estimated at about 7 ozs.; the rate of its secretion seems to be most rapid five or six hours after a meal; and its quantity decreases during sleep. The most satisfactory observations that have been made in regard to the properties of the succus entericus or secretion of the mucous membrane of the small intestine are those of Busch‡ upon a patient with an intestinal fistula. In Busch's case, in which the contents of the stomach and duodenum were completely prevented by a fistulous opening from entering the small intestine, it was clearly determined by analysis of the fæces, as well as indicated by the great improvement in the health which resulted from introducing food into the lower part of the intestine, that the fluids secreted by the jejunum, ileum, and large intestine were capable of dissolving albumen (though with the evolution of a putrefactive odour, probably due to the absence of the bile) and of converting starch into sugar. There seemed, however, to be little or no emulsifying power exerted on the fats, which were also but very slightly absorbed, the greater part reappearing in the fæces. In this case the woman lived for six weeks, previous to her coming under the care of M. Busch, upon the absorption which had taken place in the stomach and duodenum. A great portion of the products of digestion, which presented a variable reaction to test-paper, flowed off by the fistulous orifice, and she had become much emaciated. The treatment adopted was the re-introduction of this discharged fluid into the lower orifice of the fistulous opening, when she rapidly regained her health and strength. In M. Demant's case, in which a segment of the intestinal canal was isolated, the succus entericus contained no peptic or albumin-digesting ferment, as it was without action on any of the proteids; but it contained a diastatic ferment, since it converted starch into grape-sugar. It converted cane-sugar into grape-sugar, but did not act on Inulin. Fats containing free acids were emulsified, but neutral fats were unacted on. Many experiments have been made upon animals. Thiry§ isolated a loop of the small intestine in a dog preserving the vascular supply intact, and established a fistulous opening between it and the surface. The quantity of fluid obtained in this way from the loop, if calculated for the whole length of

§ "Sitz. d. k. Akad. zu Wien," Band i.

the intestine, amounted to about 1 lb. in five hours, and was of a clear straw-yellow colour, alkaline reaction, and exceedingly constant specific gravity (1·0115). It contained about 2·5 per cent. of solids, less than one-half of the amount obtained by M. Busch from his patient, of which about 1·5 consisted of albumin and other organic matters, the remainder being salts. In experimenting on the physiological effects of this fluid upon the different constituents of food, little more than negative results were obtained, no action being apparently exerted either on starch, fat, or albumin, and only a feeble power (when alkaline) of dissolving fibrin. Paschutin,* operating in a similar manner, obtained a fluid which had little or no action on any of the fats nor on the various albuminous compounds. The *infusion* of the small intestine converted starch and cane-sugar into a form of grape-sugar.† Dobroslawin‡ pursuing Thiry's method in Dogs found that the fluid secreted possessed a diastatic action on starch, requiring, however, about two hours to operate, and had a slow and feeble action on raw fibrin, which at a temperature of 100° F. was converted into peptone in the course of from 20 to 48 hours without the occurrence of any putrefactive odour. It had no action on oleaginous compounds. Schiff§ also operating after Thiry's method upon Dogs found that small portions of albumen, casein and fibrin, generally underwent conversion into peptones, and that starch was rapidly converted into sugar. Occasionally, however, perhaps owing to peculiar states of the animal's health, or to the immediate effects of the operation, these actions failed to take place.‖

131. Under normal conditions the fluid contents of the small intestines is a mixture of the salivary, gastric, biliary and pancreatic secretions with the secretion of the intestinal glandulæ, and there can be little doubt that in this part of the alimentary canal all the principal constituents of the food are reduced to a soluble condition. Here the conversion of starchy into saccharine matter is completed, the oleaginous compounds are emulsified and in part saponified, and a solvent agency is exerted even upon albuminous substances which have not been submitted to the previous agency of the gastric fluid (as has been shown by experimentally introducing pieces of meat, through a fistulous orifice, directly into the duodenum).¶ The contents of the intestines, which are highly acid in the first part of the duodenum, become gradually neutralised and then alkaline by admixture with the secretions of the liver and pancreas, but towards the lower part of the ileum it has been found that owing to lactic and butyric acid fermentations, the chyme becomes acid though the mucous membrane is alkaline to test-paper.** In a case recorded by Lossnitzer an opening existed twelve inches above the ilio-cæcal valve. After a meal of milk, bread, and a little meat, the chyme was turbid, flocculent, bright yellow, rather strongly acid, foaming, smelt of volatile fatty acids, and on standing

* "Centralblatt," 1870, p. 561.

† The infusion of the small intestine of the sheep and calf is incapable of converting cane-sugar into grape-sugar.

‡ "Untersuch. aus d. Instit. für Physiologie in Graz," 1870. Dobroslawin obtained in one case 34 grains of fluid per hour from a loop of intestine about 13 inches in length; and in another case 28 grains of fluid from a loop about 19 inches in length. The rapidity of secretion was augmented by the passage of a current of electricity. See also Eichhorst.

§ Abstract in Henle and Meissner's "Bericht," 1868, p. 168.

‖ Quincke also frequently observed the solvent action of the succus entericus upon fibrin to fail.

¶ See the account of M. Cl. Bernard's researches in the "Amer. Journ. of Med. Sci.," Oct. 1851, p. 356; Zander, "De Succo Enterico," Inaug. diss., Dorpat, 1850; and Frerichs, art. *Verdauung*, in Wagner's "Handwörterbuch," Band iii.

uickly developed gas bubbles. The fluid contained biliary acids and peptones, ut neither parapeptone nor sugar.

132. The action of the Pancreatic secretion on albuminous compounds, s already stated, terminates with the production of Leucin, Tyrosin, and sparaginic acid in the small intestines. The further changes taking place in the ower part of the ileum and in the large intestine which result in the formation f the ill-smelling compounds Indol, Skatol, and Phenol, are essentially the result f putrefactive fermentation accompanied or induced by the presence of bacteria nd other low organisms, which have been probably for the most part introuced from without. Various acids, as lactic, acetic, butyric, and baldrinic, together with glycin and certain gases, as CO_2, H_2S, H and CH_4, also make heir appearance. It is to the above acids that the acidity of the contents of he cæcum, so strongly marked in Herbivora, is usually due. In Carnivora, ccording to Bernard,* they have an alkaline reaction. That digesion of albuminous compounds will still take place, though imperfectly, n the large intestine, is shown by the observations of Steinhauser† upon a woman who had an artificial anus communicating with the large intestine. When food was introduced into the lower part of the bowel, it was for the most part discharged unaltered; but albumin was to some extent dissolved. Czerny and Latschenberger‡ have more recently had a similar opportunity in a patient who after Hernia had a fistulous orifice in the sigmoid flexure. Their experiments led them to the conclusion that although the lower part of the sigmoid flexure and the rectum in Man have no digestive power on albumin or fibrin, and no power of emulsifying fats, yet that soluble albumin and fat in the state of emulsion may there undergo *absorption* in an unaltered condition. Starch-paste was also absorbed, but they were unable to satisfy themselves whether it was first converted into sugar. The addition of common salt or of magnesium sulphate checked or altogether prevented absorption. Markwald§ experimented on a case of fistula (following hernia, patient being forty-nine years of age) of the cæcum, and had thus the whole tract of the large intestine at his disposal. The temperature of the large intestine, which was thoroughly healthy, was 37·6° C., the peristaltic movements were active. When sponges were introduced and left for two hours, a somewhat tenacious slightly-cloudy fluid of strong alkaline reaction was obtained, containing a trace of albumin which was without the slightest diastatic action on starch. Starch-paste introduced in gauze bags exhibited no conversion into sugar, even after four to six hours. When fibrin and coagulated white of egg were introduced they underwent considerable diminution (84 per cent. in twenty-six hours in the case of fibrin); putrefactive decomposition or fermentation then set in, with the production of Peptone, Tyrosin, and Indol. Absorption of peptones, as indicated by an increase of the urea, occurred late and only to a slight extent, and even water was but slowly absorbed. That the large intestine is not essential to life and health is shown by this case, in which the patient was in fairly good health after two and a-half years. Leube‖ found in a patient with Cancer of the Intestine, that whilst albumin underwent no digestive action, when introduced *per se* into the bowel, raw starch, a mixture of finely-minced meat and pancreas acquired the smell, consistence, and appearance of ordinary fæces after it had been retained in the bowel for about

twenty-four hours, and in a later communication* he recommends the employment of such a mixture with the glycerin extract of the pancreas as a means of supporting life, especially during the summer months, when the fresh gland and its juice soon lose their digestive properties by putrefaction.

133. The undigested residue of the food, mingled with the products of secretion that have been poured into the alimentary canal, gradually acquires, in the large intestine, the ordinary consistency of Fæces, through the continuance of the absorbent process, whereby the superfluous fluid is removed. The condition of this residue has been particularly studied by Dr. Rawitz and Dr. Marcet.† By the former observer, muscular fibres are stated to be almost entirely dissolved, especially in the case of fish and the hare, though less rapidly in that of poultry and other animals, only a few fragments remaining. Dr. Marcet, however, found muscular fibres, exhibiting clearly their well-marked structure, almost constantly present and in considerable quantities; and he is inclined to believe that when meat is daily taken, only the juices are extracted, the fibres themselves undergoing but little digestive action. The cells of cartilage and fibro-cartilage, the fibres of elastic tissue,‡ mucin, nuclein, and fatty matter if taken in excess, are frequently found unchanged in the fæces; and crystals of cholesterin may usually be obtained, especially after the use of pork fat.—"As regards *vegetable* substances, Dr. Rawitz states that he frequently found large quantities of cell-membranes unchanged in the fæces; also starch-cells (which were rarely seen by Dr. Marcet), deprived of only part of their contents. The green colouring principle, chlorophyll, was usually unchanged. The walls of the sap-vessels and spiral vessels were quite unaltered by the digestive fluid, and were usually found in large quantities in the fæces; their contents, probably, were removed."§—Besides the undigested residue of the food, the microscope enables us to recognise the brown colouring-matter of the bile, epithelium-cells and mucus-corpuscles, and various saline particles, especially those of the ammonio-magnesium phosphate,‖ whose crystals are well-defined; most of which are derived from the secretions.—The quantity of fæcal discharge which is daily passed by an adult seems to vary from 2 to 10 ozs. Dr. Edward Smith found the average weight in prisoners at the Coldbath Fields Prison to be 8·55 oz.¶ These men were fed upon a full dietary with brown bread, and the proportion of the fæces to the solid food was 1 : 4·5. Severe labour on the treadmill was found to diminish the quantity of fæces, whilst the rest of Sunday occasioned a considerable increase. The proportion of water was very uniform—viz., 73·5 per cent.; and an average of 41·8 grains of nitrogen

* "Centralblatt," 1872, p. 465. † "Med. Times and Gaz.," July 31, 1858.

‡ It has been pointed out to the Author by his friend Mr. Quekett, that elastic fibres are occasionally to be met with in the Human fæces, which present an appearance of transverse division (probably resulting from incipient decomposition) closely resembling that which is normal in the ligamentum nuchæ of the Giraffe. So distinct, indeed, does the transverse division then become, that these fibres, when peculiarly abundant (as they are in the fæces of persons who have for some time been living upon mutton-chops, and have not put aside the segment of the aorta which each chop includes), have actually been mistaken for a confervoid growth in the fæces.

§ Rawitz, "Ueber die Einfachen Nahrungsmittel," Breslau, 1846; and the Analysis of Wehsarg and Ihring's Inaugural Theses in "Brit. and For. Med.-Chir. Rev.," vol. xiv. p. 528.

‖ Crystals of this salt sometimes occur in perfectly normal fæces; and in those cases in which the secreted fluids and the contents of the intestine readily undergo decomposition, as in typhus, cholera, and certain forms of dysentery, they are found in large numbers and of considerable size.

¶ Sixty to 250 grammes, Landois, "Lehrbuch," 1879, p. 333, with an average of 170 grammes.

was daily eliminated from the system by this channel.* Bischoff, Meyer, and Voit† have shown that a bread diet given to dogs causes a great increase in the amount of fæces; and Brücke‡ points out that the remarkably different effects observed by different persons who have submitted themselves to the so-called Banting's cure—some of whom complain of constipation, while others suffer from diarrhœa—is referable to the fact that whilst an exclusive meat diet is apt to cause diarrhœa, it always causes great diminution in the amount of fæces excreted; readily giving rise to the idea that constipation is present. The absolute quantity of solid matter discharged in the fæces in the 24 hours is about 460 grains, of which only 10 per cent. consists of undigested matter. Of the dry fæces, from 23 to 31·5 per cent. (the proportion being smaller with meat than with vegetable diet) consists of an inorganic ash; the composition of which is stated by Enderlin§ to be as follows:—

Alkaline chlorides and sulphates	1·367	Soluble in water.
Bibasic phosphate of soda	2·633	
Phosphates of lime and magnesia	80·372	Insoluble in water.
Phosphate of iron	2·090	
Sulphate of lime	4·530	
Silica	7·940	

The potash generally predominates greatly over the soda, but especially when the diet has chiefly consisted of muscular tissue. The reaction of the Fæces is usually acid, but sometimes neutral or alkaline. The study of the composition of the Organic portion of the Fæces is attended with so much difficulty and unpleasantness, that it has hitherto been scarcely prosecuted systematically. According to the inquiries of Dr. Marcet,‖ healthy Human excrements contain—1. A peculiar substance crystallizing in acicular, silky, four-sided prisms usually grouped into stellæ, not subject to spontaneous decomposition, possessing feeble affinities, fusing at about 203° F., containing Sulphur, and having a composition expressed by the formula $C_{78}H_{78}SO_2$: this he proposes to call Excretin.¶ In infants cholesterin may take the place of excretin in the Fæces.** 2. Stearic and Margaric Acids in combination with bases, especially lime and magnesia. 3. A colouring matter similar to that of blood and urine. 4. Small quantities of peptic and amylolytic ferments. And 5. An acid olive-coloured substance of a fatty nature, termed *Excretolic* acid, which is probably united in fæces with Excretin, or a basic substance closely allied to it. Dr. Austin Flint†† obtained a substance he termed Stercorin which results from the decomposition of Cholesterin, and Vanlair and Masius‡‡ isolated a colouring matter which they named Stercobilin.§§ The fæces of infants at the breast are yellow or greenish-yellow, the reaction always acid, the consistence from almost solid to that of a thin fluid, the smell never foul, but resembling that of acid milk. They invariably contain whitish fibrin-like flocculi, and under the microscope epithelial cells, fine hairs, and crystals of the fatty acids may be observed. Wegscheider‖‖ finds that

‖‖ Wegscheider "Ueber die normale Verdauung bei Saüglinge," Berlin, 1875; and "Centralblatt," 1876, p. 47.

the albuminous substances contained in the milk are completely absorbed. The so-called Milk-detritus is not casein, but consists essentially of fat and intestinal epithelium. The fats are not completely absorbed, a part is discharged in the form of soap, a part as free fatty acids, and some perhaps in an unchanged condition. Urobilin and unchanged bilirubin are found, and in slight disorder of the bowels Biliverdin. The Cholesterin presents no peculiarity. Diastatic and pancreatic ferments are present in small quantities, but no pepsin.

134. Of the degree in which the Bile, as a whole, normally enters into the composition of the fæces, it is difficult to speak with precision. Its principal constituents can be easily recognised in the upper part of the small intestine; but the further we descend in the intestinal canal, the less of them do we meet with; and in the contents of the large intestine, and in the evacuated fæces, they are only to be discovered in small quantity. How far this result depends upon their removal from the alimentary canal by re-absorption, and how far upon the loss of their characteristic properties by decomposition, cannot be stated with certainty. According to Bischoff, jun., in the human subject about 45 grains of the biliary acids are daily discharged by the fæces; whilst, according to Voit's estimate, about 170 grains are secreted by the liver, consequently, about 125 grains must be either re-absorbed or destroyed in their course through the intestinal tube. From the experiments of Hoppe-Seyler, it would appear that in dogs whose bile chiefly contains taurocholic acid, this acid undergoes changes in passing through the alimentary canal which are identical with those produced by boiling with acids, or with alkalies, or which occur in the act of putrefaction, cholalic acid, dyslysin, and choloidinic acid being produced. On the other hand, in the fæces of those animals that, like the ox, secrete bile, of which glycocholic acid is the chief constituent, this acid being comparatively stable and scarcely destroyed even by putrefaction, may be found in considerable quantity. That the colouring matter of the fæces is in great part derived from the bile, is shown by their clayey colour when that secretion is not duly poured into the intestinal tube. And it is probable that the peculiar fatty substances usually present are products of the metamorphosis of its oleaginous and resinous matters. Cholesterin is constantly present.* The researches of Bidder and Schmidt upon the amount of *sulphur* in the fæces appear to show that not above one-eighth of the solid matter of the bile is normally excreted under this form. The indications of the presence of bile are especially distinct when the fæces have remained for only a short time in the large intestine, and when there has consequently been less time for its re-absorption. Meconium contains unaltered Bilirubin and Biliverdin, together with Glycocholic and Taurocholic acids.

135. Planer† examined the Gases developed in the alimentary canal of Dogs after different kinds of food, and in Man after death. The gas contained in the stomach consisted chiefly of air swallowed with the food, and was usually small in quantity. The Oxygen soon disappeared. In the small intestines, Carbonic Acid and Hydrogen are developed in nearly equal proportion, whether the diet be Animal or Vegetable. The appearance of these gases in the intestines is attributable to putrefactive fermentation, which is accompanied by the development of bacteria. In the conversion of starch and sugar into lactic and butyric acids there is an evolution of Carbonic Acid and Hydrogen: thus—one equivalent of Sugar $C_{12}H_{12}O_{12} = (C_8H_7O_3)\ HO + 4CO_2 + H_4$. It has been found that Hydrogen sulphide is constantly formed when the pancreatic

* Hoppe-Seyler, "Phys. Chem.," 1878, p. 336.

† Henle and Meissner's "Bericht für 1860," p. 274.

juice is allowed to act on Fibrin, but that no Hydrogen gas is disengaged unless a putrefactive ferment be present. In like manner neither Carbonic acid gas nor Hydrogen are evolved during the action of bile or of pancreatic juice on starch or fat, though both of these gases appear during their putrefaction.* In the large intestine, Carbonic Acid is chiefly present, but is mingled with Sulphuretted Hydrogen (after Animal diet), and if the food have been long retained in the body, with Carburetted Hydrogen (CH_4). In a dog which had been fed for 6 days on pure animal diet, and was killed 5 hours after a meal, he found—

	CO_2.	O.	N.	H.	SH.
In the Stomach . . .	25·20	6·12	68·68		
Small Intestine . . .	40·1	Traces	45·52	13·86	
Large Intestine . . .	74·19	0·63	23	1·41	0·77

In another dog fed with bread for 8 days, there was only sufficient gas for analysis in the small intestine; it consisted of—

CO_2.	O.	N.	H.
38·78	Traces	54·2	6·33

Ruge† has carefully examined the Gases of the large intestine in the Human subject after different kinds of food, and finds their composition tolerably constant,—Nitrogen Gas preponderating after the use of flesh, Hydrogen after milk, and Carburetted Hydrogen after Vegetable (Leguminous) diet. Though the gases were sometimes offensive, they never gave more than a trace of Sulphuretted Hydrogen. The following Table includes his chief results:—

Composition of the Gases of the Large Intestines after the use

	Of Milk, for		Of Vegetables (Leguminous), for					Of Animal Diet, for		
	1	2								
	48 hours.	72 hours.	48 hours.	72 hours.	96 hours.	2nd series of Experiments on same person.		24 hours.	48 hours.	72 hours.

In the absence of bacteria and the putrefactive process generally, no gases are found in the intestines of infants, but it appears shortly after birth, before any milk has been swallowed.‡

136. If we now cast a retrospective glance at the changes undergone by the several groups of substances employed as food in their passage through the alimentary canal, we shall find that—1. The *oleaginous compounds* are melted and finely divided in the stomach, and may, under certain conditions, even here undergo decomposition indicated by acid eructations. On entering the small intestine they are emulsified, and in part also decomposed by the action of the pancreatic juice and bile into fatty acids and glycerin. The

‡ Breslau, "Monatschrift f. Gebürts-kunde," Band xxv. p. 238.

glycerin, though not further acted upon by the pancreatic juice, yet in the lower parts of the intestine and under the influence of putrefactive ferments in an alkaline solution breaks up into succinic and other fatty acids with the evolution of H and CO_2 gases. When taken in moderate quantities the fats are almost entirely absorbed before reaching the large intestine, though a small quantity of soaps of lime in combination with stearic, palmitic, and oleic acids, may generally be obtained from the fæces. If taken in excess the fats are discharged unchanged. 2. The *Carbohydrates* are converted into dextrin and a peculiar form of sugar, first by the saliva, secondly by the pancreatic juice, and thirdly by the succus entericus, and the sugar thus formed is quickly absorbed, or if in excess, may under the influence of bacteria and the putrefactive ferments yield lactic and subsequently butyric acid. Starch may, indeed, undergo all these changes in the mere act of putrefaction without the presence of the pancreatic juice. If, however, a large quantity of starch be eaten raw, as in the form of apples or other vegetables, a considerable proportion passes off by the bowels unaltered, and this is seen even in the Herbivora which have very long and capacious alimentary tracts. Acetic acid is decomposed into CO_2 and CH_4, and Cellulose appears to undergo the same change. Malic and tartaric acids yield acetic acid and CO_2. 3. The albuminous compounds are in part absorbed directly into the blood in the stomach, but for the most part undergo conversion in this cavity by the action of the gastric juice into acid-albumin and then into peptone. As the acid chyme traverses the duodenum it becomes mingled with the pancreatic and biliary secretions, the latter of which precipitates the peptones, whilst the pancreatic ferment is incapable of acting. Gradually, however, the acidity diminishes, and when from admixture of the bile, pancreatic juice, and succus entericus, the contents of the intestine have become alkaline, the pancreatic ferment re-dissolves and resumes its activity, which is then continued throughout the alimentary tract. Pancreatic peptones are now formed; leucin, tyrosin, asparaginic* acid and CO_2 appearing as secondary products. The final changes of the albuminous compounds in the lower part of the intestine by the action of the putrefactive ferments are Indol, Skatol, and Phenol with H_2H_2S. The gelatin-yielding tissues, especially when they have been previously cooked, appear to be readily dissolved and absorbed; as are also such substances as brain, and the tissue of glands generally (liver, pancreas, thymus, and kidney). Amongst the products that have been found when gelatin undergoes putrefactive decomposition with the pancreas are CO_2 in large quantity, NH_3 acetic, butyric, and baldrianic acids, and much leucin, but neither glycocol nor indol.† Lastly, *mineral compounds*, and the various fermented beverages, are but little altered in their passage through the alimentary canal, being directly taken up by the blood-vessels and lymphatics.

* Asparaginic acid $C_2H_3(NH_2)(COOH)_2$ is bibasic, and forms thin rectangular laminæ, or minute four-sided prisms. One part dissolves in 376 of water at 0° C. and in 18°·6 of boiling water. It is insoluble in alcohol, alkaline solutions rotate to the left, acid to the right. Weiske, Schrodt, and St. v. Dangel ("Zeit. f. Biologie," Band xv., 1879, p. 287) have shown that it possesses some nutritive value, and may, like gelatin, imperfectly supply the place of albumin. It is found in the seeds and buds of many plants.

† Nencki, "Ueber die Zeresetzung der Gelatin," &c., Bern, 1876.

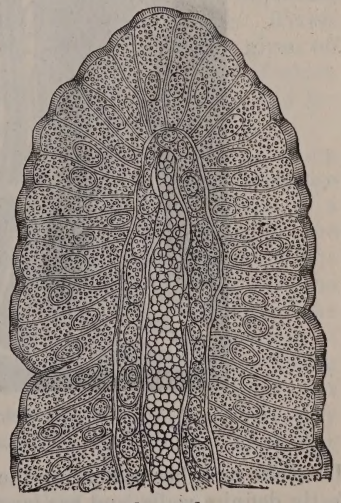
CHAPTER VI.

OF ABSORPTION AND SANGUIFICATION.

1. *Of Absorption from the Digestive Cavity.*

137. So long as the Alimentary matter remains in the Digestive cavity, however perfect may be its state of preparation, it is as far from being conducive to the nutrition of the system, as if it were in contact with the external surface. It is only when absorbed into the vessels, and carried by the circulating current through the very substance of the body, that it becomes capable of being appropriated by its various tissues and organs. In Man, as in nearly all Vertebrate animals, a set of vessels, first observed by Caspar Aselli in 1622, is interposed between the walls of the intestine and the sanguiferous system; for the purpose, as it would seem, of aiding in the taking-up of certain components of the nutritive matter, of which part at least are not in a state of perfect solution, and of preparing them for being introduced into the current of the blood. These are the *Absorbents* of the intestinal walls; of which those that are found, after the performance of the digestive process, to contain the white opalescent fluid known as 'chyle' are distinguished as *lacteals;* while the remainder, like the absorbents of the system generally, are known as *lymphatics.* The distinction is a purely artificial one; for the 'lacteals' are the 'lymphatics' of those parts of the intestinal walls which they supply, as is shown by the fact that, during the intervals of the digestive process, they contain a transparent fluid in all respects similar to the 'lymph' of other parts.—The Absorbents form a minute plexus beneath the mucous lining of the alimentary canal along its whole extent; but in the small intestine they enter the villi, at the extremities of which, indeed, they may be said to commence. Those only are entitled to the designation of 'lacteals' which originate from the intestinal canal below the point at which the biliary and pancreatic ducts pour their contents into it; for above that point, the fatty constituents of the alimentary matter are not in a state of sufficiently fine division to enter them; and the absorbed fluid is consequently pellucid, instead of possessing the milky aspect. Thus, then, we are to consider the *lacteal* portion of the Absorbent system to be that part of it which is specially adapted, by its prolongation into the villi, for the reception of an Oleaginous fluid; which we shall presently see to be taken up from the contents of the alimentary canal, and to be prepared for entrance into the absorbents, by the epithelium-cells at the radical extremities of those organs (§ 138).

Fig. 76.



c b a b c

Section of a Villus from the intestine of a rabbit: above (*a*) is the central canal, bounded on either side by the matrix (*b*), which again is covered by long columnar cells (*c*), containing a nucleus and granules. The outer border of these cells is seen to be straited.

138. The *Villi* are extensions of the mucous lining of the Intestinal canal, which thickly beset its surface from the pyloric orifice to the cæcum, that is, through the entire length of the Small Intestine, to which they are limited in Man. They have usually somewhat the form of the finger of a glove, being sometimes nearly cylindrical, sometimes rather conical, whilst they not unfrequently become flattened and extended at the base, so that two or more coalesce. Their length varies from 1-4th to 1-3rd of a line, or even more; and the broad flattened kinds are about 1-6th to 1-8th of a line in breadth.—In the upper part of the small intestine, where they are most numerous, it has been calculated by Krause that there are not less from 50 to 90 in a square line; and in the lower part, from 40 to 70 in the same area.—The details of their structure are of extreme interest in reference to the mechanism of absorption. If the plan pursued by Teichmann, that of injection, be adopted, the appearances presented are those shown in Figs. 77 and 78, taken from the beautiful plates which accompany his work on the Lymphatic System.* From these it appears that the lacteals commence either by a simple closed extremity, or by a loop, though in broad villi a network is sometimes visible.

Fig. 77.

A. Villi of Man, injected, showing the blood-vessels, and the lacteals.
B. Villus of a Sheep.

The tube or tubes occupying the centre of the villus appear to possess perfectly definite walls, and are larger than the numerous capillary blood-vessels which surround and are external to them. Their average diameter is about 1-800th or 1-1000th of an inch; but they present here and there slight dilatations and contractions, and at the base of the villus terminate in a network of lacteal vessels immediately subjacent to the Lieberkühnian follicles

* Ludwig Teichmann, "Das Saugader System," Leipzig, 1861.

(Fig. 78, *b*), termed by Teichmann, from the closeness of the meshes, the *Rete angustum*. This plexus communicates with another formed of larger vessels, which are supplied with valves, are more deeply situated in the submucous areolar tissue (Fig. 78, *c*); these constitute the so-called *Rete amplum*. Besides these plexuses, Auerbach* has more recently called attention to other plexuses of lymphatics, situated in and between the muscular coats of the intestines. In the longitudinal muscular layer one such plexus, and in the circular layer several may be found, to which he has applied the name of *interfascicular* lymphatic capillaries, all of which pour their contents into a median system of larger channels, possessing valves, and occupying the space between the circular and longitudinal muscular coats, which he has termed the *interlaminar plexus*. This last he considers represents the subserous or subperitoneal plexus of other observers, a layer which is only present at and in the immediate vicinity of the attachment of the mesentery. Some of the finest of these capillary lymphatics appear to have no other parietes than such as may be formed by the adhesion of a single layer of sinuously-contoured and tesselated epithelium-cells. In addition to the central lacteal, each villus is composed of a matrix of areolar tissue,† without any intermixture of elastic fibres, but having in its interstices numerous branched and inter-communicating cells containing nuclei, and frequently also fat-granules in their interior. The arrangement of the *blood-vessels*, according to Heller,‡ is that in man every villus contains an artery, which begins to lose itself in a capillary plexus, about the middle of the villus. The vein returning the blood begins at the point of the villus, and generally goes directly into the submucous tissue, without receiving any lateral branches. Both longitudinal and circular *muscular fibres* prolonged from the muscularis mucosæ§ are found in the villi. These surround the lacteal tubes, and their contraction, which has been frequently observed whilst absorption is going on, has an important influence on the propulsion of the fluids contained within the vessels. *Nerves* have been traced into the villi by Thanhoffer, who describes fibres given off from Meissner's plexus, ending in stellate granular cells, the processes of which penetrate the epithelial cells and are connected with their nuclei, and are partly also distributed to the muscular tissue and to the artery.‖

139. When the Villi are examined at such a period after a meal containing oleaginous matters as has sufficed for its partial digestion, their lacteals are seen to be turgid with chyle, the extremity of each being imbedded in a collection of globules presenting an opalescent appearance, and giving to the end of the villus a somewhat mulberry-like form. This appearance is due to the distension of the cylindrical epithelial cells *investing* the villi with the lacteal fluid. As it is a matter of much interest to examine and explain the mode in which absorption in this, its first stage, is effected, the attention of many observers has been directed to the structure of these columnar investing epithelial cells; and if the observations of v. Thanhoffer¶ be correct, our knowledge of the mode of absorption of various substances, and especially of those of an oleaginous nature, will be materially simplified. According

to this investigator,* the villi (*c*, Figs. 80 and 81, *a*, Fig. 82) are invested by a single layer of columnar cells, with a *broad free*, and a *narrower attached* extremity. The free extremity presents a thickened, bright, and highly refractile border surrounding the open mouth of the cell. The border varies in thickness and breadth in different cells, even of the same villus; and when the cells are examined from above, their margins seem to be continuous with each other, so that a kind of mosaic is formed. Immediately internal to the border (or perhaps projecting from the whole of the free surface of the cells)

is a row of processes formed of the protoplasmic contents of the cell, which in mammals are rod-like or vertically striated, but in frogs, especially when examined in winter, are ciliaform and perform vibratile movements, which are particularly distinctly seen if the surface of the intestine have been brushed over with bile, and after division of the spinal cord or dorsal nerves. The processes quickly disappear after death, being replaced by a globular swelling projecting from the mouth of the cell, occasioned by the imbibition of water. The cells of the large intestine possess no bright border.

* See Heidenhain in Moleschott's "Untersuchungen," Band iv. 1858, p. 251; and Brücke in id. Band viii. 1862, p. 495; and in "Denkschrift. d. k. Akad. d. Wiss. zu Wien," Band vi. p. 105. Also Verson in Stricker's "Human and Comparative Histology," Syd. Soc. Transl. vol. i. 1870, p. 573. Ranvier, art. 'Epithelium' in the "Nouveau Dictionnaire de Médecin," t. iii. 1870. v. Thanhoffer, Pflüger's "Archiv," 1874, p. 391. These epithelial cells were described by MM. Gruby and Delafond ("Comptes Rendus," 1843, 1195) as possessing cilia on their free margin; but Kölliker, Funke, and more recently Schultze, considered this appearance as illusory, and produced by the thick membrane closing the free extremity of the cell being perforated by very delicate pores or canals, whilst after death it split up in such a manner as to *resemble* a bundle of cilia (Kölliker, "Mikroscop. Anat.," 1860, p. 329). Balogh, agreeing with Kölliker as to the lines in question being canals, differed from him in believing them to be not pre-existent, but merely the indications of the passages made by the molecules of fat in penetrating the delicate tissue occluding the mouth of the cell (Moleschott's "Unters.," Band vii. 1861, p. 556). Brettauer and Steinach, on

The *contents* of the cells during fasting are a mass of clear protoplasm, and a bright nucleus with nucleolus; but during digestion, especially of substances containing fat, the protoplasm becomes cloudy or granular, from the entrance of the molecules of oil into its substance; a process that is facilitated by the movement of the processes above described. The *attached extremity* runs out into two kinds of processes, one of which is continuous with stellate corpuscles (*d*, Fig. 80), forming a lymph canalicular system in the connective tissue matrix of the villus, which opens into the central lacteal vessel (*e*), thus affording a direct means of entrance for the fat molecules into the absorbent system, and explaining the occasional introduction of solid particles into the circulating current, whilst the other (*e*, Fig. 82) appears to be nervous tissue, since it is connected with a corpuscle resembling a ganglion cell, and has the chemical relations of nerve. It penetrates the foot of the cell, and has been traced by Thanhoffer to the nucleus. Interposed at variable distances between the ordinary columnar cells, are peculiar oval cells, known as *Cup- or Goblet-cells* (Fig. 81, *a*). These have been regarded by Letzerich* as the true commencements of the absorbent system. He traces a connexion between their attached attenuated extremities, with a vascular network lying between the basement-membrane of the villus, which joins the central lacteal, and states that after a meal containing oleaginous material the flask-shaped bodies, or cup-cells, the delicate and more internally situated plexus of absorbent vessels, and the central lacteal may all be seen charged with oily particles.†

140. In regard to the degree in which the function of Nutritive Absorption is performed by the Lacteals and by the Sanguiferous system respectively, considerable difference of opinion has prevailed. When the Absorbent vessels were first discovered, and their functional importance was perceived, it was imagined that the introduction of alimentary fluid into the vascular system took place by them alone. Such an idea, however, would be altogether inconsistent with the facts of Comparative Anatomy;‡ and it is completely negatived by the results of experiment. Absorption is effected to a very considerable amount by the agency of the Blood-vessels, as is shown

whose observations the statements of Brücke, Heidenhain, and other later authors are founded (Brettauer and Steinach, "Sitzungsbericht d. k. Akad. d. wissen. zu Wien," 1857, Band xxiii. p. 303), maintained that the apparent cilia are prolongations of the cell-contents, the cells themselves terminating with a smooth circular margin. They described the columnar arrangement as broadest and most distinct in fasting animals, whilst in cells filled with fat it diminishes to one-half or one-third of its former breadth, and the striæ disappear, so that only a bright narrow rim or border is left. Lastly, Wiegandt is stated in Canstatt's "Jahresbericht" for 1862, p. 32, to view the cilia as merely the optical expression of striæ or wrinkles.

* Virchow's "Archiv," Band xxxix. 167, p. 435.

† These statements of Letzerich have met with much opposition. Lipsky ("Wiener Sitzungsber.," Band lv. p. 183), Erdmann ("Die Resorptionswege," &c.), and Sachs (Virchow's "Archiv," Band xxxix. p. 493), regard the cup cells as the results of manipulation, and deny their original existence altogether. Others, as Oeffinger (Reichert's "Archiv," 1867, p. 337), and Thanhoffer (op. cit.), whilst admitting their presence during life, believe they proceed from natural changes occurring in the ordinary epithelial cells, such as imbibition of water, &c. Others, again, as Schultze ("Archiv f. Mikroskop. Anat.," Band iii. pp. 145 and 204), and Theod. Eimer, in whose little pamphlet ("Die Becherzellen") the reader will find an interesting epitome of all the essays (thirty-seven in number) on this subject up to 1868, are of opinion that there is a real and primary difference between the columnar cells and the cup cells, and they regard the latter as *mucus-secreting organs*. Verson (op. cit.) leaves the question undecided. It is right to add that some observers believe that oleaginous particles enter the substance of the villus between the epithelial cells (Fortunatow, Pflüger's "Archiv," Band xiv. 1877, p. 285; and Herbert Watney, "Quart. Journ. of Mic. Sci." 1877, p.204). For the latest views see Klein and Noble, "Atlas of Histology," 1879, p. 16.

‡ See "Princ. of Comp. Phys.," chap. iv.

in the first place, by the readiness with which water and saline solutions and even alcohol are taken up from the parietes of the Stomach, and are carried into the general circulation. Thus in a case of extroversion of the bladder, observed by Mr. Erichsen,* in which the urinary secretion could be collected immediately on its passing from the kidney, when a solution of ferrocyanide of potassium was taken into the stomach, this salt was detected in the urine in one instance within 1 minute, and in three other instances within $2\frac{1}{2}$ minutes. In the interesting experiments of Dr. Bence Jones and Dr. Dupré,† the rapidity of absorption of certain salts from the stomach is shown to be very great, a few grains of lithium chloride given to a fasting guinea-pig diffusing itself through all the vascular textures, and even into the cartilage of the hip-joint, in the short space of 15 minutes, and permeating every part of the lens, even in old animals, in four hours. In like manner, from experiments on cataractous lenses in man, it appears that traces of quinine may be discovered in the lens in about $2\frac{1}{4}$ hours after its ingestion. In the analogous eperiments of Eulenberg‡ and of Colin,§ iodide of p otassium, when injected into the stomach, could be detected in the parotidean saliva in from 20 to 45 minutes, and when into the small intestine of a horse in so short a period as 6 minutes in the chyle. In all these cases, however, the stomach may be presumed to have been empty, and the vascular system in a state of aptitude for absorption; since the experiments were made either after a long fast, or at least four hours after a light meal. When, on the other hand, the salt was introduced into the stomach soon after the ingestion of alimentary substances, a much longer period elapsed before it could be detected in the urine; thus, when a substantial meal had been taken two hours previously, the interval was 12 minutes; when tea and bread-and-butter had been taken one hour previously, the interval was 14 minutes; a similar meal having been taken 24 minutes previously, the interval was 16 minutes; when only two minutes had passed since the conclusion of such a meal, the interval was 27 minutes; and when a solid meal had been concluded just before the introduction of the salt, the interval was 39 minutes.—These facts are of great importance, in showing the very marked influence which the state of the *stomach* exercises upon the absorption of matters introduced into it. Not less important, however, is the state of the *vascular system* in regard to turgescence or emptiness; for it was found by Magendie, that when he had injected a considerable quantity of water into the veins of a dog, poison was absorbed very slowly; whilst, if he relieved the distension by bleeding, there was speedy evidence of its entrance into the circulation. If a small quantity of a concentrated solution of any salt, even if this possess a high endosmotic equivalent, be introduced into the stomach or intestine, it undergoes so much dilution that it is rapidly absorbed into the blood, but if a very large quantity be ingested osmosis in the opposite direction takes place, and diarrhœa results.—The rapidity with which not only aqueous but alcoholic liquids introduced into the stomach may pass into the general circulation has been shown by the experiments of Dr. Percy,‖ who found that, when strong alcohol was injected into the stomach of dogs, the animals would sometimes fall insensible to the ground *immediately* upon the completion of the injection, their respiratory and

cardiac movements ceasing within two minutes; and that on post-mortem examination in such cases, the stomach was nearly empty, whilst the blood was highly charged with alcohol; thus rendering it almost certain, that not merely the final destruction of nervous power, but the immediate loss of sensibility, was due to the action of alcoholized blood upon the nervous centres.—Finally, numerous experiments have been made by various physiologists, which have demonstrated that absorption of alimentary and other substances may take place from the walls of the Stomach; these substances having been prevented from passing into the intestine by a ligature around the pylorus. Now, as the Absorbent system does not present that peculiar arrangement in the coats of the stomach, which it does in those of the intestinal tube, there can be little doubt that the introduction of such substances into the system must be effected chiefly, if not entirely, through the medium of its sanguiferous capillaries.

141. That the Blood-vessels of the *Small Intestine* largely participate in the introduction of soluble alimentary matter into the system has been clearly proved by various observations upon the constitution of the blood of the Mesenteric veins; these having shown, that after the digestion of albuminous and farinaceous or saccharine substances, albuminose, dextrin, grape-sugar, and lactic acid, are detectible in that fluid, whose usual composition is greatly altered by the presence of these substances, as well as by the augmented proportion of water which it contains. Again, it has been found that even after complete obstruction to the entry of the chyle into the circulation by ligature of the thoracic ducts, the digestion and absorption of albumin still take place, as indicated by the continued well-being of the animal and the appearance of the usual amount of nitrogen in the urine.* Moreover, it is asserted by Bruch,† that so large a quantity of fat is absorbed into the blood-vessels, that the superficial capillary network sometimes presents an opalescent whiteness. We may consider the Sanguiferous vessels, then, as affording the usual channel by which a large part of the nutritive materials are introduced into the system; but these are not allowed to pass into the general current of the circulation, until they have been subjected to an important *assimilating* process, which it appears to be one great office of the Liver to perform, whereby they are rendered more fit for the purposes they are destined to serve in the economy. Of this we shall have presently to speak.—The absorbent power which the blood-vessels of the Alimentary canal possess, is not however limited to alimentary substances; for it is through them almost exclusively that soluble matters of every other description are received into the circulation. This, which may now be considered a well-established fact, was first clearly shown by MM. Tiedemann and Gmelin,‡ who mingled with the food of animals various substances, which, by their colour, odour, or chemical properties, might be easily detected in the fluids of the body: after some time the animal was examined; and the result was, that unequivocal traces of such substances were not unfrequently detected in the venous blood and in the urine, whilst it was only in a very few instances that any indication of them could be discovered in the chyle.

142. It is a very remarkable fact, which has recently been fully substantiated, that not merely soluble matters, but insoluble substances in a state of minute division, may find their way from the alimentary canal and

* Schmidt-Mulheim, "Archiv f. Anat. u. Phys., Phys. Abth.," Band i. p. 549.

† Siebold and Kölliker's "Zeitschrift," April, 1853.

‡ "Versuche über die Wege auf welchen Substanzen aus dem Magen und Darmkanal in Blut gelangen," Heidelberg, 1820.

from the serous cavities into the current of the circulation. Thus, it was found by Oesterlen,* that particles of finely-divided charcoal, introduced into the alimentary canal, could be distinguished in the blood of the mesenteric veins; and similar results were obtained by Eberhard, and by Mensonides and Donders,† not only with charcoal, but also with sulphur and even with starch, the latter substance being at once detectible in the blood by the iodine-test. Such substances enter the lacteal system either through or between the epithelial cells of the villi. In favour of the former view is the fact that the presence of psorosperms in the interior of these has been distinctly perceived by Klebs.‡ In like manner, Ludwig and others in the Physiological School of Leipsic§ have noticed the penetration of particles of colouring matters from the interior of the abdominal or thoracic cavities into the lymphatics of the central tendon of the diaphragm, and into those of the pleura respectively; Auspitz‖ describes a similar absorption of starch corpuscles from the *peritoneal* cavity, and it seems probable that this is effected through certain openings (*stomata*) first noticed by Oedmannson,¶ and since fully described by Klein and others, which occupy interspaces between the ordinary tesselated epithelium-cells lining the serous cavities. These openings, therefore, establish a direct communication between the serous cavities and the lymphatic vessels, and the cavities themselves may reasonably be regarded, in one sense, as merely colossal dilatations of the vessels, analogous to those large lymph sacs or reservoirs which are found in the frog, fish, and other animals.**

143. There seems to be no reason for doubting that the absorption of the various nutritive and alimentary materials takes place according to the ordinary rules of Osmosis; for on the one hand is the aliment always more or less perfectly reduced to the liquid state, the density of which is generally less than that of the blood, in consequence of the very copious discharge of aqueous fluid into the alimentary canal during the operation of digestion; and on the other is the blood or lymph in rapid movement, possessing a high specific gravity, at a temperature of 99° or 100° F.; whilst between them is the septum, of immense extent and great tenuity, formed by the mucous membrane, and the walls of the blood or lymph vessels: the tendency is, therefore, in accordance with the general principles of osmosis to favour the passage of the aliment from the intestinal tract towards the circulating fluids.

Absorption of Albuminous Compounds.—As regards such substances as albumin, gum, and gelatin, which belong to the "colloid" class of substances, and therefore transude with extreme difficulty, it appears at first sight difficult to explain how they pass through the intestinal mucous membrane.††

†† Mialhe ("Chimie appliquée à la Physiologie," 1856) broke the shell from the end of an egg, leaving the membrane intact, and immersed it in water. After 5 hours it had increased in weight upwards of 30 grains, and the membrane was tight and prominent. The water in which the egg had been immersed became alkaline from the exosmose of the salts, but no albumin had escaped. So Graham and Eckhard ("Beiträge," Band iii. pp. 51 and 85, 1862) state that in analogous experiments with solutions of gum no exosmosis of that substance occurred.

The experiments of Funke, however, show that the act of digestion essentially effects a conversion of the "colloid" group into the "crystalloid;" for that as soon as the albuminous substances introduced into the stomach have undergone the modification into peptones, they have acquired the power of traversing animal membranes with comparative facility. As the conditions for the absorption of these substances are alike present in the stomach and intestines, it is probable that this process takes place through the whole length of the alimentary tube, though chiefly in the intestine, as the presence of acids is unfavourable to its active performance; a view which receives support from the experiments of Busch* upon the woman with a duodenal fistula, in whom it was found that a considerable portion of the saccharine, and about one-third of the albuminous compounds taken as food, were absorbed before reaching the intestines. Funke† observed, also, that when solutions of peptone were introduced and secured by ligature in determinate lengths of the intestines of living rabbits, and permitted to remain for two, four, and six hours, the more concentrated the solution, the greater was the activity with which the absorption was accomplished in a given time; but that a remarkable difference occurred from what might have been anticipated, where a definite quantity of the solution of peptone was presented to double the extent of surface, very little more being then absorbed, or at least nothing like double the amount in the same time. He further found that the amount absorbed in the living animal by no means stands in direct relation to the duration of the experiment, the process taking place with far more energy during the first hour than subsequently; and the same facts were also observed in experiments upon the absorption of sugar made by Becker.‡ The peptones are absorbed by both the lacteals and the blood-vessels, but their absorption proceeds slowly as only small quantities can be obtained from the chyle and portal blood, and as they have to restore the waste of all albuminous compounds they are probably speedily reconverted into albumin. The presence of common salt enables even raw albumin to be absorbed to some extent. If great excess of albumen be ingested, it appears in the urine.

Absorption of Fats.—Fats and oils are absorbed from the intestinal canal chiefly in the form of emulsion, partly also in the form of soaps. A certain quantity only is taken up, but the amount increases with the time during which digestion is progressing. If an excess be ingested, it is discharged unaltered in the fæces. The absorption is chiefly effected in the small intestine, since under ordinary circumstances little is found in the cæcum or colon. No difficulty exists in accounting for the absorption of soaps, but the oils and neutral fats could not penetrate a membrane moistened with water, unless some special provision existed by which this difficulty could be overcome. This provision is found in the bile, for it has been shown by various observers that if the entrance of bile into the intestines be prevented, a far smaller proportion of fat is absorbed, whilst it is well known that the bile aids in the formation of a fine emulsion, and Wistinghausen and Steiner§ have shown that such an emulsion will pass far more readily than oil through a moist animal membrane under a given pressure. It is probable that each particle of oil becomes surrounded by a layer of bile, and then partly by capillarity,‖ partly

‖ The importance of bile in aiding capillary attraction is shown in an experiment made

by the mechanical pressure exerted by the intestinal walls,* and partly, perhaps, by the action of the protoplasmic rods and processes of the intestinal cells,† gains entrance into their interior, from whence it is forced onwards by the periodical contraction of the muscular tissue of the villi themselves.‡ That in the case of the solid fats they must be capable of becoming fluid at the temperature of the body, and of forming an emulsion before absorption can be effected, is shown by the experiment of Funke, who found that stearin, the melting-point of which is 63° C., was not absorbed when introduced into the intestines of animals. The size of the oil drops is of considerable importance; the yolk of egg, for instance, mingled with two or three times its weight of water, will traverse the mucous membrane of the intestines at 100° F. with ease at a low pressure; but M. Morin§ experienced much difficulty with milk on account of the comparatively large size of the droplets. Adult cats are capable of absorbing about 0·6 grammes of fat every hour for each kilogramme of their weight; young cats about 0·92 gramme; dogs about 0·465 gramme; and geese about 0·8 gramme. The fats are taken up by both the lacteals and the blood-vessels.

Absorption of Carbohydrates.—Starch being insoluble, is not absorbed in the small intestine. The grape-sugar into which it is converted by the action of the diastatic ferments of the salivary, pancreatic, and intestinal glands is, however, almost entirely taken up in this part of the alimentary tract, 96 per cent. disappearing in the course of two hours. Cane-sugar which is in part also converted into grape-sugar is absorbed by both the lacteal and the blood-vessels, though very small quantities can be obtained from any given specimen of the chyle or from the blood of the portal vein at any particular moment. If taken in such excess that the quantity absorbed into the blood amounts to 0·6 per cent. of the blood, it appears in the urine.

144. *Absorption in the Large Intestine.*—Under ordinary circumstances, with the absence of villi and the change in the arrangement of the lymphatic system, it is probable that little besides water is absorbed from the aliment in the cæcum and colon. Up to the ileo-cæcal valve the contents of the intestinal tube are usually fluid, but beyond this point their consistence increases by the withdrawal of water till they assume a semi-solid form. It is well known that the life of patients, in whom from disease the entrance of food into the stomach is difficult or impossible, may long be sustained by the administration of nutritive enemata. Leube‖ has investigated the process of absorption that takes place under these circumstances, and has shown that albuminous compounds, especially in the form of peptones, as when minced muscle and pancreas are introduced into the rectum, a considerable quantity is absorbed, indicated by the improvement in the general condition of the patient by the increase in the weight of the body, and in the amount of urea eliminated by the kidneys, and by the actual diminution in the weight of the mass of nutritive material placed in the bowel. The addition of common salt, and of fat, providing it does not exceed one-sixth of the total weight, facilitates the process of absorption. Eichhorst¶ found that peptones, muscle, casein, salified

by Wistinghausen, in which two glass tubes having a diameter of 0·825$^{mm.}$ were placed vertically in olive oil. The interior of one of the tubes was wetted with distilled water, and in this the oil rose by capillarity 1·75$^{mm.}$ The interior of the other was moistened with bile, and in it the oil rose 11$^{mm.}$, or nearly six times higher.

¶ Pflüger's "Archiv," 1871, Band iv. p. 570.

egg albumin, and gelatin were absorbed to a greater or less extent when injected into the large intestine. But pure egg albumin and coagulated fibrin were not absorbed. Bauer* observed that whilst little or no albumin is absorbed from the large intestine even when it has been well whipped, a considerable quantity is taken up if a little common salt has been added to it. In Voit and Bauer's experiments on a dog† white of egg underwent little or no absorption *unless* a little common salt were added; serum, albumin, syntonin, and peptones were taken up in larger but still small quantities. The amount of oil absorbed was also small, and they were unable to maintain life for any very long period by means of injections.

2. *Absorption from the Body in general.*

145. The Mucous Membrane of the alimentary canal is by no means the only channel through which nutritive or other substances may be introduced into the circulating apparatus from external sources. The *Lymphatic* system is present in all animals which have a *lacteal* system; and the two, as already pointed out, evidently constitute one set of vessels. The Lymphatics, however, instead of commencing on the intestinal walls, are distributed through most of the vascular tissues of the body, and especially in the Skin; but their number bears no proportion whatever to the vascularity of the several tissues, or to the amount of interstitial change which these undergo; and it would rather seem to be related to the amount of Connective tissue interposed between the other constituents of the fabric. Thus, we find the Nervous centres entirely destitute of them, unless, indeed, they are represented by the lacunar spaces filled with nuclei, which have been described by Robin‡ and His§ as surrounding the capillaries; and they are very scanty in the substance of Muscles. After passing, like the lacteals, through a series of glandular bodies (the precise nature of which will be presently considered), they empty their contents into the same receptacle with the lacteals; and the mingled products of both pass into the Sanguiferous system.—We find in the Skin, also, a most copious distribution of capillary blood-vessels, the arrangement of which is by no means unlike that of the blood-vessels of the alimentary canal; and its surface is further extended by the elevations that form the sensory papillæ, which are in many points comparable to the intestinal villi, although their special function is so different.

146. In the lowest tribes of animals, and in the earliest condition of the higher, it would seem as if Absorption by the *external surface* is almost equally important to the maintenance of life, with that which takes place through the internal reflexion of it forming the walls of the Digestive cavity. In the adult condition of most of the higher animals, however, the special function of the intestinal tract is so much exalted as usually to supersede the necessity of any other supply; and the function of the cutaneous and pulmonary surfaces may be considered as rather that of exhalation than of absorption. We have a remarkable exception to this general statement, however, in the case of Frogs and other Batrachia, which are characterized by the softness of their skins and the thinness of their epidermic covering; for cutaneous absorption seems in them to be no less active than their cutaneous exhalation and respiration are well known to be. And even in the higher animals there

* "Sitz. d. k. Bayer. Akad.," 1868, Band ii. p. 511.

§ "Zeits. f. wiss. Zoologie," 1865, p. 127.

are peculiar conditions of the system in which the imbibition of fluid through these surfaces is performed with great activity, supplying what would otherwise be a most important deficiency. It may take place either through the direct application of fluid to the surface, or even through the medium of the atmosphere, in which a greater or less proportion of watery vapour is usually dissolved. This absorption occurs most vigorously when the system has been drained of its fluid, either by an excess of the excretions, or by a diminution of the regular supply.

147. It may be desirable to adduce some individual cases, which will set this function in a striking point of view; and those may be first noticed in which the Absorption took place through the contact of *liquids* with the skin. It is well known that shipwrecked sailors and others who are suffering from thirst, owing to the want of fresh water, find it greatly alleviated, or altogether relieved, by dipping their clothes into the sea and putting them on whilst still wet, or by frequently immersing their own bodies.*—In a case related by Dr. Currie, of a patient labouring under dysphagia in its most advanced stage (the introduction of any nutriment, whether solid or fluid, into the stomach having become perfectly impracticable), an attempt was made to prolong his existence by the administration of nutritive enemata, and by immersion of the body, night and morning, in a bath of milk and water. During the continuance of this plan, his weight, which had previously been rapidly diminishing, remained stationary, although the quantity of the excretions was increased. How much of the absorption, which must have been effected to replace the amount of excreted fluid, is to be attributed to the baths, and how much to the enemata, it is not easy to say; but it is important to remark that "the thirst, which was troublesome during the first days of the patient's abstinence, was abated, and, as he declared, removed by the tepid bath, in which he had the most grateful sensations." "It cannot be doubted," Dr. Currie observes, "that the discharge by stool and perspiration exceeded the weight of the clysters;" and the loss by the urinary excretion, which increased from 24 ozs. to 36 ozs. under this system, is only to be accounted for by the cutaneous absorption.†—Dr. S. Smith mentions that a man, who had lost nearly 3 lbs. by perspiration, during an hour and a quarter's labour, in a very hot atmosphere, regained 8 ozs. by immersion in a warm bath at 95°, for half an hour.‡—The experiments of Dr. Madden§ on his own person show that a positive increase usually takes place in the weight of the body during immersion in the warm bath, even though there is at the same time a continual loss of weight by pulmonary exhalation, and by transudation from the skin.‖ This increase was, in some instances, as much as 5 drachms in half an hour; whilst the loss of weight during the previous half hour had been $6\frac{1}{2}$ drachms: so that, if the same rate of loss were continued in the bath, the real gain by absorption must have been nearly an ounce and a half. Why this gain was much less than in the cases just alluded to, is at once accounted for by the fact that there was no deficiency, in the latter case, of the fluids naturally present in the body.

* See a collection of such cases in Dr. Madden's "Experimental Enquiry into the Physiology of Cutaneous Absorption," p. 47.

† "Medical Reports," vol. i. pp. 308–326.

‡ "Philosophy of Health," vol. ii. p. 396.

§ Op. cit. pp. 59–63.

‖ That part of the function of Cutaneous Transpiration, which consists in simple Exhalation, is of course completely checked by such immersion; but that which is the result of an actual Secreting process in the cutaneous glandulæ (chap. xiv. sect. 4) is increased by heat, even though this be accompanied with moisture.

148. There are certain phenomena, which, if accurately recorded, cannot be accounted-for in any other way than by admitting that, under particular circumstances, a considerable amount of water may be absorbed from the *vapour* of the atmosphere. The following are among the most satisfactory and circumstantial observations that have been adduced in support of this position:—Lining observed that his body on one occasion increased in weight, during two hours, to the amount of 8½ ozs.; allowance being made for the amount of fluid ingested during that time, and for the quantity passed off by the urine and by cutaneous transpiration.* Dr. Jurin affirms that he ascertained an increase of 18 oz. to have taken place during a night passed in a cool room, after a day's exercise and abstinence.† It is stated by Dr. Watson,‡ that a lad at Newmarket, having been almost starved, in order that he might be reduced to a proper weight for riding a match, was weighed at 9 A.M., and again at 10 A.M., and he was found to have gained nearly 30 oz. in weight in the course of this hour, though he had only drunk half a glass of wine in the interim. Nearly the whole of the increase must here be attributed to absorption of vapour from the atmosphere; probably, however, rather through the lungs than through the skin. If the possibility of such absorption be admitted, we are probably to attribute to it the chief part of the excess of watery fluid which cannot be otherwise accounted for, in the following instances:—Dr. Hill§ relates the case of a diabetic patient, who for five weeks passed 24 lbs. of urine every twenty-four hours; his ingesta during the same period amounted to 22 lbs. At the commencement of the disease, he weighed 145 lbs.; and when he died, 27 lbs. of loss had been sustained. The daily excess of the excretions over the fluid ingesta could not have been less than 4 lbs.; making 140 lbs. for the thirty-five days during which the complaint lasted. If from this we deduct the amount of diminution which the weight of the body sustained during the time, we still have 113 lbs. to be accounted for, which can only have entered the body from the atmosphere.—A case of ovarian dropsy has been recorded by Mr. Ford,‖ in which it was observed that the patient, during eighteen days, drank 692 ozs. or 43 pints of fluid, and that she discharged by urine and paracentesis 1298 ozs. or 91 pints, which leaves a balance of 606 ozs. or 38 pints to be similarly accounted for.¶

149. The capacity of the Skin to absorb saline or other substances in solution is comparatively small, for no trace of Iodine can be detected in morning urine, when a bath containing half an ounce of potassium iodide dissolved in 80 gallons of water has been taken after six hours' abstinence from food.** M. Willemin, and others,†† have demonstrated that the healthy skin is capable of absorbing not only water, but small portions of various substances soluble in water; the process of absorption varying under

¶ In this case, however, as in others of a similar kind, something is to be allowed for the quantity of water contained in the solid food ingested; but this may be fairly considered not to exceed the quantity lost by pulmonary and cutaneous exhalation, and discharged in the fæcal evacuations.

different circumstances, and often taking place very slowly, but being favoured by a delicate skin, and by exhaustion, though it does not take place when the skin is actively perspiring from exercise. The occasional serious effects upon the urinary organs of the application of a blister, the poisonous action of solutions of strychine, nicotin and digitalin,* the tinging of the urine with madder, rhubarb, and turmeric after bathing in infusions of those substances,† and, lastly, the remarkable experiment of Schreger, who found on immersing the hind leg of a puppy for 24 hours in tepid milk, after having previously applied a bandage, that the lymphatics were full of milk, though the veins contained none, all show that the skin possesses distinct but feeble powers of absorption. Homolle,‡ whilst admitting that pure water is certainly absorbed, and that saline solutions and some organic mixtures are sometimes decomposed by the skin, apparently by that tissue exerting an elective affinity for one of the constituents, to the exclusion of the others, states that in many instances in which he remained for an hour or more at a time in baths containing 3 ozs. of cyanide or iodide of potassium, nitrate of potash, or chloride of ammonium, he was unable to discover any trace of those salts in the urine, nor did he perceive any physiological effect from the employment of baths in which 1 lb. of belladonna or of digitalis leaves had previously been infused. The absorption of solid bodies (rice starch) and of mercury can be effected by rubbing them strongly into the skin, and is materially facilitated by the addition of any oily substance.§ When absorption does take place, we should expect that the absorbed substances would be more readily discoverable in the absorbents than in the veins; for their imbibition takes place entirely according to ordinary physical laws, in conformity with which they pass most readily into the vessels which present the thinnest walls and the largest surface.‖

150. Our inferences with regard to the ordinary functions of the Lymphatic system, however, must be rather drawn from the nature of the fluid which it contains, and from the uses subsequently made of it, than from such experiments as the preceding. We shall presently see that there is a close correspondence in composition between the Chyle of the Lacteals and the Lymph of the Lymphatics; the chief difference being the presence of a considerable quantity of fatty matter in the former, and of a larger proportion of the assimilable substances (albumin and fibrin) which are equally characteristic of both (§§ 154, 155). The close resemblance between the contents of the Lymphatics and diluted Liquor Sanguinis seems to indicate that the former are chiefly derived from the fluid portion of the blood, which has transuded through the walls of the capillary vessels, and has permeated the tissues, giving up to them the materials required for their nutrition. And we shall presently see reason to believe that this transudation answers the additional purpose of subjecting the crude materials, which may have been taken up direct into the blood-vessels, to an elaborating or preparatory agency, such

‖ For much interesting information respecting the increased energy, rapidity, and certainty of action of various poisons introduced directly into the circulation by the hypodermic mode of injection, as compared with the effects of the same substances when administered by the stomach, see the 'Report of a Committee of the Medico-Chir. Soc.' in vol. v. of the "Transactions" of that Society.

as it seems to be the especial object of the Lacteal system to exert upon the nutritive substances which *it* serves to introduce into the circulation.—But it seems not impossible that there may be another source for the contents of the Lymphatics. We have already had to allude, on several occasions, to the disintegration which is continually taking place within the living body; whether as a result of the limited duration of the life of its component parts, or as a consequence of the decomposing action of Oxygen. Now the *death* of the tissues by no means involves their immediate and complete destruction; and there seems no more reason why an animal should not derive support from its own dead parts, than from the dead body of another individual. Whilst, therefore, the matter which has undergone too complete a disintegration to be again employed as nutrient material is carried off by the excreting processes, that portion which is capable of being again assimilated may be taken up by the Lymphatic system. If this be the case, we may say with Dr. Prout, that "a sort of digestion is carried on in all parts of the body."—It may be stated, then, as a general proposition, that the function of the Absorbent System is to take-up, and to convey back into the circulating apparatus in a state of higher elaboration, such substances as are capable of appropriation to the *nutritive* process; whether these substances be directly furnished by the external world, or be derived from the disintegration of the organism itself. We have seen that in the Lacteals the selecting power is such that these vessels are not disposed to convey into the system any substances but such as are destined for this purpose; and that readily diffusable matters are absorbed in preference by the mesenteric Blood-vessels. The case is different, however, with regard to the Lymphatics; for there is reason to believe that they are more disposed than the venous capillaries to the absorption of other soluble matters, especially when these are brought into relation with the skin, through which the Lymphatic vessels are very profusely distributed.

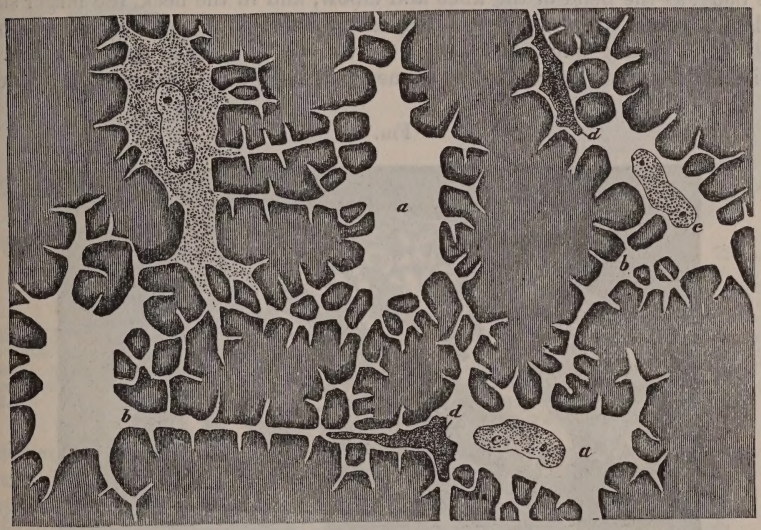
3. *Of the Elaboration of the Nutrient Materials.—Sanguification.*

151. The alimentary substances, taken up by the Blood-vessels and Absorbents, seem very far from being capable of immediate application to the nutrition of the body; for we find that they are not conveyed by any means directly into the circulating current, but that those which enter the Gastro-intestinal veins are submitted to the operation of the Liver, whilst those which are received into the Lacteals are subjected to a kind of glandular action within their own system; the newly-absorbed materials in both cases undergoing considerable changes, which tend to assimilate them to the components of the Blood.—The Lymphatic System* consists of an extensive network of vessels very generally distributed throughout the body, but present in remarkable abundance beneath the Skin and Mucous membranes. In regard to their origin it has been shown (§ 138) that in the villi the lymphatics end in processes like the finger of a glove, which, however, are probably connected laterally with irregular passages, containing stellate cells, through which the fluids absorbed gain entrance into their interior. In other parts of the body, as in fibrous and tendinous tissues, in membranes and fasciæ, a peculiar system of branched cavities is almost always visible when proper methods of preparation and observation are adopted. Each of the cavities contains a

* For an exhaustive account of the Anatomy of which, see v. Recklinghausen, Stricker's "Human and Comp. Histology," 1870, vol. i. pp. 297–346. See also Klein, "Anatomy of the Lymphatic System," 1873–74. I. Serous Membranes.

nucleated mass of protoplasm, which completely fills it; and both the cavities and their contents are in continuity with each other, so as to form a network which is now known under the name of *lymph-canalicular* system,* and the more or less branched cells contained in them are termed *lymphatic cells.*†

Fig. 83.



Cornea of Frog treated with lunar caustic.—*a*, canalicular system. In one place a branched flattened corneal corpuscle with its nucleus is seen; in two others are lacunæ of the canalicular system, containing nuclei *c*, of corneal corpuscles and *d*, migrating or wandering cells; *b*, branched channels, which connect the lacunæ of the canalicular system. Oc. 3, Obj. 9.

The large cavities and vessels with which the lymph-canaliculi communicate appear to be always lined, whilst their walls are sometimes exclusively formed by a delicate layer of flattened epithelial cells.‡ An external membrane is in the latter case gradually acquired, as the vessels become larger, on which again is superimposed a layer of dense connective-tissue, in which a few transverse muscular fibres may be distinguished. It is a peculiarity of the Lymphatics that they do not present the same smooth and regular contour, nor the same definite mode of branching, that is met with in the Blood-vessels; on the contrary, they run irregularly, and the walls of the vessels often present dilatations or reservoirs in their course, whilst the larger vessels formed by the reunion of several smaller ones, often again subdivide and reunite. The principal communication between the lymphatics and the blood-vessels is at the point where the great trunks empty themselves into the junction of the subclavian and jugular veins. It is not improbable, however, that in certain regions, as the cornea, the lymphatic canaliculi form channels by which the fluid parts of the blood, without its morphological constituents, can enter the

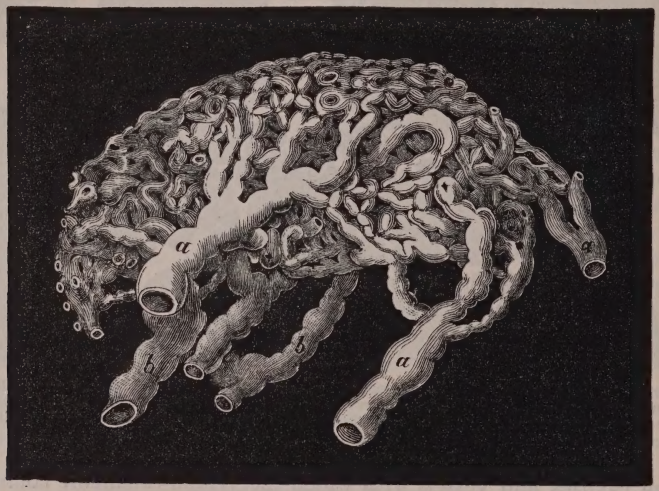
rootlets of the lymphatic system.* In many parts, especially in the central parts of the nervous system, the blood-vessels run in the interior of the lymphatic vessels, which form, as it were, an additional sheath to them, the place between the wall of the lymphatic vessel and that of the blood-vessel being occupied with fluid containing lymph corpuscles. At certain parts of the body, as the bend of the knee and elbow, and in the neck, the larger stems suddenly break up into a dense interlacing network of capillary vessels, most distinct in young subjects, forming a *rete mirabile*, as is shown in Fig. 84. This is surrounded by condensed connective tissue, and is penetrated by blood-

FIG. 84.



A section of a simple Rete Mirabile, viewed from the surface.—*a*, *a*, afferent vessels; *b*, *b*, efferent vessels only partially visible, from the popliteal space. (Man.)

vessels, constituting, so to speak, the first step towards the formation of a lymphatic gland. From this simple structure we can readily ascend through a series of gland-like organs, gradually increasing in complexity, composed of several of these little retia, arranged either continuously or in groups, until at length, by steps of easy transition, we arrive at the complex structure of the true lymphatic glands.†

Every lymphatic gland is invested by a vascular sheath or capsule of condensed connective tissue (*a*, Fig. 86), which is continuous with the coats of the afferent and efferent vessels, sending inwards a number of thin lamellæ, so disposed and connected together as to constitute a tolerably regular alveolated framework pervading the gland, excepting usually near the centre. The septa thus formed contain in Man and many other animals, but especially in the Ruminants, numerous muscular fibre-cells, *d d*, Fig. 87. The alveoli are most distinct near the surface of the gland, *c c*, Fig. 85; towards the centre, in

* See Dr. T. A. Carter, "Journal of Anatomy and Physiology," 1870, vol. iv. p. 97.

† The details of the structure of the lymphatic glands have been most laboriously investigated and excellently described by His ("Untersuch. über den Bau der Peyerschen Drüsen," Leipzig, 1862), Kölliker ("Gewebelehre," 1866), Teichmann (Op. cit.), Frey ("Untersuch. üb. die Lymph-drüsen," Leipzig, 1861), v. Recklinghausen (Stricker's "Hum. and Comp. Hist.," Syd. Soc. Trans., 1870), and Krause ("Allgemeine und Mic. Anatomie," 1876).

consequence of the breaking up and irregular disposition of the septa, they are not very apparent. The centre of the gland is occupied by the medullary

substance, varying considerably in amount in different instances, but always most abundant in childhood, and in the more deeply-seated glands. Its relation to the alveoli may best be understood by conceiving it to be a plastic substance, accumulated in mass at the centre, which sends out on all sides prolongations of the most irregular form and shape, which do nearly, but *not completely*, fill the alveoli. Spaces are consequently left between the septa which form the alveoli, and the processes of medullary substance partially filling them. These are termed the investing spaces (Frey) or lymphatic sinuses (His) of the follicle, and are represented by *b* in Figs. 86 and 87. They are traversed by irregular fibres, formed of nucleated cells with anastomosing prolongations, *c c*, Fig. 87. According to v. Recklinghausen,* they are lined by epithelial cells of a round polygonal form, and certainly contain numerous lymph-corpuscles. They are directly continuous with the afferent and efferent vessels, and may be filled with injection pro-

* See also Bizzozero, "Centralblatt," 1873, p. 110.

pelled from either of those sets of tubes; though, of course, on account of the valves, more readily through the former than the latter. The course which the lymph takes in traversing these somewhat lacunar spaces around the medullary substance contained within the alveoli is termed by Frey the superficial lymph-path. The central or medullary portion consists of a close network or reticulum of connective-tissue fibres, *a*, Fig. 87; in the interstices of which are numerous lymph-corpuscles. It is not bounded by any definite membrane, though a kind of investing wall is formed by the connective-tissue fibres being much more closely arranged near the surface; fluids, therefore, which are circulating through the superficial lymph-path (*b*) Figs. 86 and 87, may also slowly percolate through the medullary portion, and this constitutes the deep lymph-path of Frey. The medullary portion is freely supplied with blood-vessels. It thus appears that the lymph or chyle entering one of the mesenteric glands passes, under ordinary circumstances, from the afferent to the efferent vessels, through the superficial lymph-path, that is, chiefly through the investing follicular spaces around and between the alveoli: though partly also through the interstices of the tissue forming the medullary portion of the gland, where it comes into intimate relation with the blood-vessels, and takes up a certain proportion of lymph-corpuscles. When, however, the activity of the gland is at its height, as regards both the circulation of the blood and that of the lymph, as after food, the pressure of the increased quantity of the lymph effects the dilatation of the minute pores by which the spaces between the connective-tissue corpuscles and their prolongations communicate with the alveolar investing spaces. A much more rapid percolation of the newly-absorbed fluid is thus permitted through channels in which lymph-corpuscles are abundantly contained, effecting the first steps in its assimilation to the blood, into which it is subsequently poured, and of which it is obvious that it constitutes the pabulum.*

152. In immediate connection with the lymphatics are the large sacs or cavities known as the *Serous membranes*, which, as the researches of Klein† have shown, may be regarded as lymphatic glands that have been unravelled or opened out, and which present many points of interest in reference to the processes of sanguification. The serous membranes, typical examples of which are presented by the Pleura, Peritoneum, Pericardium, Arachnoid and Tunica Vaginalis, as well as by the Synovial membranes of joints and bursæ and the membrane lining the arteries and veins, are composed of a matrix of connective-tissue, lined by a single layer of cells termed the endothelium. They form closed sacs, and are found between parts that are subject to friction, the movements of which they facilitate by the extreme smoothness and lubricity of their surfaces. The endothelium for the most part consists of a layer of flattened nucleated hyaline cell-plates, the sinuous outlines of which can be brought beautifully into view by staining with nitrate of silver. In many places, however, the cells present a different character, being polyhedral, club-shaped, or even short-columnar with granular contents and ovoid nucleus, which is often constricted or divided into two. These germinating or young endothelial cells sometimes form projecting and pedunculated masses, and some of them, closely resembling lymph-corpuscles, may be seen either simply attached to the general surface, in the act of separating from it, or actually free in the cavity of the membrane. The matrix of the serous membranes,

* Oidtmann analysed a lymphatic gland from the inguinal region of an old woman and found it to consist of water 71·5, and solids 28·5, of which last 1·2 parts were salts.

† "The Anatomy of the Lymphatic System." I. The Serous Membranes. 1873.

best seen in such a part as the omentum, is composed of a homogeneous substance, in which are imbedded cells of various kinds. These, according to their form and arrangement, present (in the omentum of the rabbit, for example) two kinds of lymphangial structures. In one there are patches of more or less flattened branched cells lying in the lymph-canalicular system, multiplying by division and growing up into lymphoid cells which are also contained in the lymphcanalicular system. In the second kind there are patches and tracts, the matrix of which consists of a reticulum, containing in its meshes a variable number of lymphoid corpuscles. These patches are usually vascularized, but the former do not originally contain blood-vessels, though they subsequently become highly vascular; by coalescence they ultimately form large tracts. It is thus apparent that there is a considerable amount of adenoid tissue imbedded in, or rather forming the walls of, the serous membranes. The proper *lymphatics* of serous membranes form wide vessels, which partly accompany and sometimes invaginate or surround, and partly run independently of the blood-vessels, and their walls consist of only one layer of fusiform endothelial plates. The larger ones generally have valves and sacculated dilatations. The existence of stomata or openings on the surface of the serous membranes leading into lymphatic vessels, and forming therefore a communication between the cavity of the serous sac and the interior of the lymphatic vessels, has been clearly demonstrated. Dr. Klein distinguishes two kinds, the true and the false. The true,

FIG. 88.

which are ciliated in the female frog and toad, are either the mouths of vertical lymphatic channels, which are lined by a special layer of polyhedral cells containing granular protoplasm, and lead into the lumen of a superficial lymphatic vessel, or they represent a discontinuity between the endothelial cells of the surface leading into a simple lymphatic sinus near the surface, lined on

one side only with epithelium. The false or pseudo-stomata are perpendicular processes which extend from the superficial cells of the cell-network of the matrix of certain nodules, and pass up between the endothelial cells of the surface.

153. The whole of the *Lacteal* and *Lymphatic* system, with the serous cavities in connection with it, may thus be looked upon as constituting one great *Assimilating Gland*, dispersed through the body at large; for it does not differ in any essential particular from what the Kidney or the Testis would be, if it were simply unravelled, and its convoluted tubuli spread through the entire system, yet still all discharging their secreted products by a common outlet. In the cold-blooded Vertebrata, the Absorbent system *appears* to attain a relatively greater development than it does in the higher classes; but the difference really lies in the greater extension, in the former, of those glandular elements which are more concentrated in the latter (See PRINC. OF COMP. PHYS., §§ 184—187).—Scattered through the whole length of the intestinal mucous membrane, from the Stomach to the Rectum, are certain peculiar bodies, which are known as *Peyer's Glands*. These may be either 'solitary' or 'agminated;' the former being very generally distributed throughout the intestinal canal, whilst the latter, in number from 20 to 80, are restricted to the small intestine, being most abundant at the lower part of the ileum. In whatever portion of the canal they may occur, they are always limited in situation to that part of its periphery which is opposite to the mesentery. Each 'Peyerian gland,' in a healthy mucous membrane, presents the appearance of a circular, white, slightly-raised spot, about a line in diameter, over which the membrane is usually less beset with villi, and is very often entirely destitute of them; and it is surrounded by a ring of openings, which are the orifices of a set of cæcal follicles disposed in a zone around it (Fig. 89). The 'Peyerian patches' (Figs. 89, 90) present aggregations of these spots, varying in number from 30 to 100 in a square centimeter (=·394 of an inch), but every one of their individual components having precisely the same structure as the solitary gland. This appears to be a sort of capsule, whose walls are composed of indistinctly-fibrillated connective tissue with interspersed nuclei, and whose contents are thus but imperfectly differentiated from the tissues in which the gland is imbedded. The contents of the glands are made-up of an adenoid or cytogenous tissue, the meshes of which contain lymph corpuscles, and fatty and albuminous molecules of various size; altogether presenting an appearance of being the seat of rapid changes of progressive metamorphosis. Each follicle is surrounded by a large lymphatic sinus,* beneath which is a close vascular network; capillary vessels pass freely into the midst of its contents, and then loop back, as shown in Fig. 90.† The

† Kölliker, "Mikroskopische Anatomie," Band ii. § 171.

researches of Teichmann* show that these bodies are never penetrated by any lacteal vessels, though their presence in the mucous membrane occasions considerable disturbance in the usual arrangement of the lacteal system. The figures on page 180 show clearly the relations which they hold to the surrounding vessels, together with the general structure of the small (Fig. 78) and large intestine (Fig. 79). In their course through the mesentery, the Lacteals pass into the bodies known as the *Mesenteric Glands*, which stand in the same relation to them that the *Absorbent Glands* of the body generally do to the Lymphatics.

154. *Composition and Properties of the Chyle and Lymph.*—The chief chemical difference between these fluids consists in the much smaller proportion of solid matter in the Lymph, and in the almost entire absence of fat, which is an important constituent of the Chyle. Lymph is found in the lymphatic

* Teichmann's investigations were chiefly made by means of injections; but His, who examined thin sections of the intestinal mucous membrane after merely washing them with water and a camel-hair brush ("Untersuch. über den Bau der Peyerischen Drüsen," Leipzig, 1868, p. 7), maintains the elaborate system of vessels described by Teichmann to be only splits or fissures in the membrane between the follicles, traversed by fibrous cords and bands, and containing blood-vessels. At the same time he agrees with the view that they serve as channels for the conduction of the chyle. He considers that the proper substance of the parietes of the follicles is continuous with that of the villi and subjacent portion of the mucous membrane; both consisting of a matrix of areolar tissue with nucleated cells imbedded in it, and of capillaries, the latter being sparingly distributed to the follicles, causing them to appear like clear spaces in fine sections. He applies the term adenoid tissue to the matrix of the follicles, and to the surrounding tissue of the intestinal mucous membrane. The Lieberkühnian Glands are imbedded in this adenoid substance, and immediately external to them is the muscular layer (Brücke) of the mucous membrane. He believes lastly, that the cells imbedded in the adenoid substance become blood-corpuscles.

system generally, and in the chyliferous vessels in the intervals of digestion; in the large serous cavities, as the peritoneum, pleura, and pericardium in the lymphatic ganglia, and in the interstices of the connective-tissues, and of the tendons and aponeuroses.* It may be obtained in large quantities by dissecting out and fixing a canula in the thoracic duct just before it discharges itself into the junction of the jugular and subclavian veins.† Lesser obtained by this means 300 cub. cent. of lymph from a dog in the course of four hours, and Colin no less than 95 kilogrammes 286 grammes in twenty-four hours from a cow. The quantity of lymph which can be obtained from the head and neck of the dog is estimated by Krause‡ at one-third, and by Weiss§ at one-fifth of the weight of those parts; but these proportions are probably too high for the body generally; other experiments of Weiss showing that it varies from one-fifth (after an abundant supply of milk) to one-twelfth of the total weight. Bidder and Schmidt‖ estimated that in man nearly thirty pounds of mingled lymph and chyle are daily poured into the subclavian vein. Lymph is, in general, a colourless transparent fluid, sometimes yellowish, and sometimes turbid or opalescent, having a faint odour, salt taste, and alkaline reaction. Its chemical characters, according to Ludwig, vary considerably at different periods, and even in different parts of the system at the same time; so that of the fluids taken from the two sides of the neck it will sometimes happen that one will coagulate spontaneously, whilst the other remains fluid. Examined under the microscope, lymph is found to consist of a fluid containing corpuscles of various kinds and of different size. Some of these are very minute oil globules, and are found to be most abundant after food; others are small masses of protoplasm which present some peculiarities, according to whether the lymph has been obtained from the vessels of a cold or of a warm-blooded animal. The lymph-corpuscles of the frog are spheroidal when quiescent, and may either remain so, or if carefully watched in a moist cell for some minutes may be found to throw out at ordinary temperatures amœboid processes, to flatten and extend themselves, and to again assume a spheroidal form, or owing to the mass of the cell following one or more of the processes, to execute slow movements of progression. It would hence appear that they have no cell-wall. After the lapse of a day or two, if the slide be again examined, some of the corpuscles appear spheroidal and unaltered; others are more or less irregular, the indications of their former amœboid movements; others present one or several nuclei, surrounded by granulations composed of oil; and others, lastly, have excrescences on their surface to which the term "sarcodic" has been applied, and which differ from the amœboid processes in being spherical,

FIG. 91.

smooth, and homogeneous, and in remaining stationary when once emitted. Ranvier regards these bullæ as an indication of the death of the cell.* On the addition of iodized serum the corpuscles assume either a greenish-yellow or a port-wine colour, in the latter case owing to the presence of glycogen, and the nucleus and granulations quickly appear. A one per-cent. solution of picro-carminate of ammonia rapidly kills the corpuscles, brings their nuclei and granulations into view, and then stains them. A solution of carmine in ammonia of similar strength acts more slowly, but ultimately the nuclei become stained, and the same may be said of other colouring matters. Dilute solution of alcohol added to lymph proves immediately fatal to the corpuscles which assume the spheroidal form, emit sarcodic bullæ, and present well-defined nuclei; these when examined under a high power are found to be vesicular, to possess a double contour, and to contain one or more bright nucleoli. The nucleus is often so long that it becomes curved or twisted, or spirally coiled, so that the parts being in different planes give the impression of two or three nuclei. In different corpuscles all the stages of fission of the nuclei may be observed, and the act itself has been observed by Ranvier† in the lymphatic corpuscles of the axolotl. When the nucleus of any corpuscle has undergone division, the two or more nuclei formed seem to control the movements of the protoplasm by which they are severally surrounded, and to lead to the division of the mass, which, however, itself plays an active part, so as to form two new corpuscles. The entire process in one case occupied, at a temperature of about 62° F., three hours. The effect of heat on the corpuscles is distinctly exciting; it not only quickens their actions and renders them more energetic, but even when after removal from the body they appear to be dead, the application of moderate heat will cause their movements to recommence. At temperatures above 104° F. they soon die, becoming spherical, and exhibiting their nuclei. The presence of air or oxygen is requisite for the continuance of the movements after their removal from the body, even under favourable conditions of temperature and moisture, and oxygen appears to excite them. A moderately-strong current of electricity passed through them causes them to become spherical, whilst a strong current kills them and brings out the nucleus, though this may in part be due to the electrolytic action of the current. The lymph-corpuscles absorb blood-corpuscles or any minute foreign particles into their interior, as may easily be shown by injecting vermilion into the vessels before withdrawing the fluid. The corpuscles are not only able to seize upon and absorb neighbouring particles, but they can penetrate porous septa, as may be well seen by introducing a fragment of pith into the dorsal sac of a frog. In the course of twenty-four hours they will be found to have made their way in large numbers through the porous walls of the most superficial cells, and in less numbers into the deeper-lying cells. The latter die and speedily undergo fatty degeneration, accounting for the fatty deposit observed by Wagner and Middeldorf‡ in spongy bodies introduced into the serous cavities or into the tissues. The chief differences that are observable between the lymph-corpuscles of warm-blooded animals and those just mentioned are that they do not present amœboid movements at ordinary temperature, though at about 100° F. they are very active, the processes, however, being shorter. At 104° F. they suddenly assume the spherical form, and the nucleus and granulations appear. In their relations to oxygen, iodine, and other agents, they closely resemble the lymph-corpuscles of the frog.

‡ Pitha and Billroth, "Handbuch der Chirurgie," 1865, vol. i. p. 338.

Ritter has counted 8200 corpuscles in one c. cm. of lymph taken from a dog. The number is always less in the peripherally situated than in the more central lymphatics. After being set free in the lymphatic glands the corpuscles are carried towards the vascular system in the larger lymphatics and in the thoracic duct, floating in a fluid which contains but little oxygen. The corpuscles then consequently become spherical and motionless, and have no tendency to escape. As soon, however, as they have entered the blood, they are brought into immediate relation with a highly oxygenized fluid and acquire activity, but being rapidly carried on have no tendency to stop or create an obstruction. But when from some morbid condition of the blood-vessels they accumulate at any point, they make their way out of the vessels, and the supply of oxygen being feeble, remain quiescent and form pus-cells. A knowledge of the physiological characters of the lymph-corpuscles is of great importance in medicine, since these bodies play an important part in many pathological conditions, and the results of treatment in the early stages of inflammation largely depend on the influence of the remedies employed on their movements and life. Chemically, the *lymph-corpuscles* consist of albumins and the soluble paraglobulin, and lecithin, nuclein, cerebrin, glycogen, cholesterin, and fat have been obtained from them. The *lymph plasma*, like that of the blood, contains fibrinogen, fibrino-plastic substance and ferment, probably derived from the lymph-corpuscles, and on standing forms a soft coagulum floating in lymph-serum. *Lymph-serum* contains alkali albuminate, precipitable by acids; serum albumin, coagulable by boiling; pepton, especially in the chyle; urea, leucin (0·1 – 0·2 per cent.: Wurtz); sugar and iron (2 per cent.: Colin). Some lymph taken from a peripheral lymphatic* contained about 97 per cent. of water, 2 of albumin, 0·2 of fibrin, and 0·8 of extractives. Another specimen taken from the thoracic duct yielded 94 per cent. of water, 4 of albumin, 1 of fibrin, and 1 of extractives. Chyle from a criminal contained 90·5 per cent. of water, albumin 7, fibrin a trace, fat 1, extractives and salts 1·5. Sugar, lactates, and a diastatic ferment (Grohé) have been observed in it. Hammarsten† found about 30–32 per cent. of gas in the lymph, of which nearly the whole was carbonic acid, the quantity of nitrogen being 1 per cent., whilst there was only a trace of oxygen.

155. In fasting animals, the composition of the *Chyle* appears to resemble very closely that of the Lymph, but during digestion its qualities sensibly alter. The characters of the *Chyle* drawn from the larger absorbent trunks, near their entrance into the Receptaculum chyli, are very different from those of the fluid first absorbed into the Lacteals; for during its passage through these vessels and the Mesenteric glands it undergoes important alterations, which gradually assimilate it to Blood. The chyle drawn from the lacteals that traverse the intestinal walls contains serum-albumin in a state of complete solution with paraglobulin and casein; but it is generally destitute of the power of coagulation, no Fibrin being present in it. The salts, also, are completely dissolved; but the oily matter presents itself in the form of globules of variable size.‡ It is generally supposed that the milky colour of the chyle is owing to these; but Mr. Gulliver has pointed out§ that it is really due

* For further analysis, see Appendix.

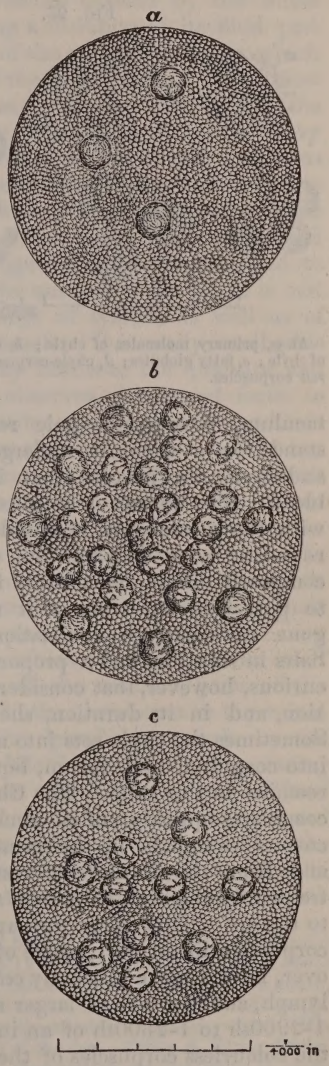
‡ These oil globules are more abundant in the Chyle of Man and of the Carnivora than in that of the Herbivora; their diameter has been observed to vary from 1-25,000th to 1-2000th of an inch.

§ Gerber's "General Anatomy," Appendix, p. 88; and "Hewson's Works" (Sydenham Society Edition), Notes to pp. 82–88; and College Lectures in "Med. Times and Gazette,' 1863.

to an immense multitude of far more minute particles, which he describes as forming the *molecular base* of the chyle (*a*, Figs. 92, 93). These molecules are most abundant in rich, milky, opaque chyle; whilst in poorer chyle, which is semi-transparent, or opaline, the particles float thinly or separately in the transparent fluid, and often exhibit the vivid motions common to the most minute molecules of various substances. Such is their minuteness that, even with the best instruments, it is impossible to form an exact appreciation either of their form or their dimensions. They seem, however, to be generally spherical; and their diameter may be estimated at between 1-36,000th and 1-24,000th of an inch. Though remarkable for their unchangeableness, when subjected to the action of numerous reagents which quickly affect the proper Chyle-corpuscles, they are readily soluble in ether, the addition of which causes the whole molecular base instantly to disappear, not a particle of it remaining; whence it may be inferred that they consist of oily matter, which is partly in the condition of neutral fat and partly saponified. That they do not ordinarily tend to coalesce, is probably due to the coating of albumin which they obtain through their diffusion in an albuminous fluid; if, however, this be dissolved by acetic acid, or even when water is added, many of the molecules are lost sight of, and oil-drops appear in their place. The milky colour which the Serum of blood always exhibits in healthy subjects during the most active period of digestion is due to an admixture of this molecular base with the circulating fluid.

FIG. 92.

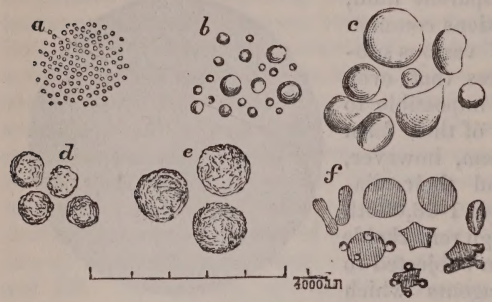


Molecular Base and Corpuscles of Chyle. At *a*, from a lacteal on the intestine; *b*, from a mesenteric gland; *c*, from the receptaculum chyli. From a man.

156. During the passage of the Chyle through the absorbents on the intestinal edge of the mesentery, towards the mesenteric glands, its character changes in several important particulars. The presence of Fibrin-factors begins to manifest itself by the slight coagulability of the fluid when withdrawn from the vessels; and a few chyle- or cytoid-corpuscles make their appearance; though these may occasionally be observed in the chyle from a lacteal on the wall of the intestine. The corpuscles are most abundant in the chyle of the mesenteric glands, and become less numerous again in the fluid of the thoracic duct (compare *a*, *b*, *c*, Fig. 92). The average diameter of these bodies is about 1-4600th of an inch. During digestion they are seen to be accompanied by much of the fatty molecular base of the chyle (*a*, Figs. 92, 93), some particles of which

have coalesced to form larger ones, surrounded by a thin layer of albumin (*b*, Fig. 93). Two, three, or more of the corpuscles may be sometimes seen enclosed within a common cell. The true Chyle-corpuscles appear to be at first in the condition of nuclei (*d*, Fig. 93), which take origin in the lymphatic glands of the mesentery; as these develop the cellular character becomes very distinct, and the nucleus may be plainly seen in the interior, especially after the addition of a little water or acetic acid. They exhibit the same changes of form as the colourless corpuscles of the blood, which are perhaps only the same bodies in a more advanced stage. The chyle drawn from the lacteals that intervene between the Mesenteric glands and the Receptaculum, possesses a pale reddish-yellow colour; and, when allowed to stand for a time, it undergoes a regular coagulation, separating into *clot* and *serum*, a process that is materially accelerated by the addition of blood. The former is a consistent gelatinous mass, which, when examined with the microscope, is found to include the corpuscles, each of them surrounded by a delicate film of oil; the fibrin of which it is principally composed differs remarkably from that of the Blood in its inferior tendency to putrefaction; whence it may be inferred that it has not yet undergone its complete vitalization. The serum contains the Albumin and Salts in solution, and a proportion of the Corpuscles suspended in it. It is curious, however, that considerable differences in the perfection of the coagulation, and in its duration, should present themselves in different experiments. Sometimes the chyle sets into a jelly-like mass, which, without any separation into coagulum and serum, liquefies again at the end of half an hour, and remains in this state. The Chyle from the Receptaculum and Thoracic duct coagulates quickly, often almost instantaneously; and few or none of the corpuscles remain in the serum. The fluid drawn from the Thoracic duct, and from the Absorbent vessels which empty their contents into it, is frequently observed to present a decided red tinge, which increases on exposure to the air. This tinge appears to be due to the presence of Red blood-corpuscles in an early stage of formation.* The ordinary corpuscles, moreover, have a more distinctly *cellular* character than have those of the chyle and lymph, and they are of larger size, their diameter usually ranging from about 1-2900th to 1-2600th of an inch: in these particulars they correspond with the colourless corpuscles of the Blood; as also in the change they exhibit on the action of acetic acid, which brings into view two, three, or four distinct central particles.

Fig. 93.



At *a*, primary molecules of chyle; *b*, secondary molecules of chyle; *c*, fatty globules; *d*, chyle-corpuscles; *e*, pale cells; *f*, red corpuscles.

157. The *movement of the fluids* taken up by the absorbent vessels seems to depend upon a combination of different agencies. The lower Vertebrata are provided with 'lymphatic hearts,'† or pulsatile cavities, by which important

* See Gulliver, "Med. Times and Gaz.," vol. ii. 1863, p. 449.

† See Wharton Jones on 'Lymphatic Heart of Eel,' "Proc. Roy. Soc.," Nos. 98 and 101, 1868; and John Priestley, "Journal of Physiology," vol. i. p. 1.

assistance is given to the onward flow; but no such aid is afforded in Man or in the Mammalia; yet it is obvious that a considerable *vis a tergo* must exist—since, if the thoracic duct be tied, it is speedily distended below the ligature, even to bursting. The main agent in effecting the movement in these animals appears to be the constant and considerable pressure exerted by the blood against the inner surface of the vessels, effecting a filtration of its fluid portions into the irregular cavities and interspaces of the connective tissue which are now believed to constitute the true origin of the Lymphatics. This view receives support from the experiments of Tomsa,* who has shown that the injection of serum into the vessels immediately after death, at the ordinary pressure of the blood, is followed by the filtration of a fluid closely analogous to lymph in its characters, which can readily be obtained from the lymphatic vessels. Abundant evidence exists to show that those circumstances which tend to increase the pressure in the capillaries, either by forcing more blood into any part,† or by preventing its return by ligature or pressure applied to the veins (provided that complete stoppage of the current of the blood is not produced), are followed by an increased discharge of lymph, as well as of lymph-corpuscles‡ from the larger absorbent vessels. It is easily intelligible that various other causes besides pressure may influence the quantity and quality of this fluid, which, as Milne-Edwards§ observes, is poured forth to *irrigate* the various organs of the body; for besides the important condition of the quality of the blood (with the effects of variations in which we are but imperfectly acquainted), differences in the thickness of the walls of the vessels and of the external pressure to which they are subjected, may to some extent be the causes of those differences in the nature of the transudate observed in Hydrocephalus, Ascites, and Hydrocele.‖ In the Lymphatics as well as in the Lacteals of the higher animals, the onward course of the contained fluids is probably aided by the contraction of the unstriped muscular tissue in their walls, assisted by the action of the valves; and to this perhaps we may attribute the emptiness of the absorbent system which usually presents itself some little time after death. Moreover, in all the movable parts of the body, material assistance is afforded (as it is to the circulation in the veins) by the occasional pressure exercised upon the lymphatic vessels by the muscles and other surrounding tissues; for while this pressure is operating it will tend to empty them of their contents, which are only permitted by the valves to pass in one direction; and when the pressure is relaxed they will be refilled from behind. In the lacteals, special agents for the propulsion of the chyle exist in the muscular fibres contained in the villi, which constitute so many minute force-pumps that are perhaps stimulated to

* The Serum used in Tomsa's experiments contained from 6·77 to 6·26 per cent. of solid residue, and that obtained from the Lymphatics from 6·12 to 4·36 per cent., which is about the proportion in ordinary lymph. Paschutin, however, has arrived at a different conclusion, and believes that variations in the arterial pressure have no influence on the flow of lymph. The secretion is increased, and its composition altered by the administration of curare. His experiments were made on the lymphatics of the fore leg of the dog. "Sitz. d. König, Sächs. Gesellsch. d. Wiss.," 1873, p. 95. For corroborative observations see Genersich in idem, 1870, and Emminghaus, Ludwig's "Arbeiten," 1873, Band viii. p. 51.

† As was effected by Mr. Robinson in his experiment recorded in the "Med.-Chir. Trans.," vol. xxvi. p. 51, when the aorta just above its division into the common iliacs, and also one of the renal arteries, were tied, and albumin immediately made its appearance in the urine, being as it were forced by the increased pressure in the remaining renal artery, through the delicate filter formed by the walls of the vessels in the Malpighian tufts.

§ See his excellent chapter on Transudation in the "Leçons sur la Physiologie," vol. iv. 1859, pp. 391–446. ‖ See Hales's "Hæmastatics," pp. 118–119.

action (as suggested by Schiff) by the irritating properties of the bile. When the lacteal and lymphatic fluids have arrived at the thoracic duct, besides the forces already mentioned, their flow receives an additional impetus from a *vis a fronte* derived in part from the suction-power exerted by the rapid movement of the blood in the subclavian veins, the influence of which may readily be proved experimentally, and partly from the negative pressure exerted upon the walls of the duct during the period of inspiration, the opposing influence of expiration being neutralized by the valves.* Noll† found the pressure in the larger lymphatics of the neck in cats and dogs to be equal to that of a column of water varying from $\frac{1}{2}$ to $1\frac{1}{4}$ inch in height (10—30 mm.), but it is probably much higher in the smaller vessels. The rapidity of the current in the lymphatics of the neck is stated by Weiss to be about one-sixth of an inch per second.

That the *central nervous system* exercises considerable influence over the process of absorption is clearly shown by the experiments of Goltz.‡ In these, which were made upon frogs, rendered motionless by curare, the brain and spinal cord were removed in some instances, whilst in others they were left intact. In both sets of frogs fluid was injected into the dorsal lymph sac, and it was found that the fluid was rapidly carried off in those in which the brain and spinal cord were uninjured, whilst little or no absorption took place in those in which those organs had been removed. Nasse,§ who has also investigated this subject, found that irritation of sensory nerves caused increase in the flow of lymph. Excitation of the pneumogastric trunk, or of its central extremity when divided, augmented the flow. The influence of the nervous system is, however, in all probability *only indirect*, being due, in Goltz's experiments, to the circumstance that in the uninjured animals the circulation was maintained, whilst in those deprived of their nervous system the vessels of the body generally had lost their tone, and the blood accumulated in the veins of the abdomen and in other parts to such an extent indeed that little blood escaped even when the aorta was divided. In Nasse's experiments, again, the effects of the irritation of the sensory nerves was doubtless to cause contraction of the small vessels. The results of Krause's and Tomsa's experiments likewise lead to the conclusion that the influence of the nervous system is indirect, for whilst Tomsa found that irritation of the nerves proceeding to the testicle produced no alteration of the quantity, Krause obtained, both upon irritation of the mucous membrane of the mouth—that is to say, on irritation of the fifth pair of nerves—as well as on excitation of the portio dura, a considerable increase in the flow; the different effect in the two cases being clearly the result of the intermittent pressure of the *muscles* in the parts traversed by the lymphatics in the one instance, and the entire absence of muscles in the other.

158. Vascular or Ductless Glands.—There is reason to believe that the office performed by certain bodies connected with the Sanguiferous system, which possess the essential elements of the Glandular structure without any efferent ducts, is to restore to the circulating current any substances which they may withdraw from it; and there seems adequate ground, therefore, for the conclusion, that their action, whatever it may be, is subsidiary to the process of Sanguification,—being exercised, perhaps, upon that portion of the

nutrient materials more especially, which did not traverse the Absorbent system when first introduced, but which was directly taken-up by the Blood-vessels. The organs in question are the Spleen, and the Thymus, Thyroid, and Supra-renal bodies. Of these the Spleen deserves especial notice, on account of its size and its obvious functional importance in the adult; the others appearing to minister more particularly to the requirements of the system at the earlier periods of life.

The principal points in the minute structure of the Spleen that may be regarded as established are that* it is essentially divisible into a lymphatic portion and a blood-vascular portion;† the former being represented by the Malpighian bodies and the sheaths of the arteries, the latter by the spleen-pulp. The whole is enclosed in a fibrous investment. These parts may be separately considered:—

I. The *fibrous coat* in Man is composed of white fibrous tissue, with an intermixture of yellow or elastic fibres, and a few fusiform non-striated muscular fibre-cells, especially at those points where the trabeculæ are given off from the capsule. The *trabecular tissue* consists of bands and threads of fibrous tissue, which arise from the inner surface of the fibrous envelope. The fibres form a network that extends through the entire organ, and they are connected with the sheaths of the vessels. They are almost entirely muscular in the dog and in those animals which have much muscular tissue in the external envelope. The spaces left by their intersection, which are by no means regular as to either form or size, are occupied by the splenic corpuscles and splenic parenchyma.

II. The *Arteries* of the Spleen form no anastomoses, but subdivide and ramify like the branches of a tree, with the Malpighian corpuscles attached to them as fruit (Fig. 95). Beyond their connection with these, however, they enter the general mass of the splenic parenchyma; and here each twig subdivides into a tuft of arterioles still more minute, which either pass directly into small veins (Billroth) or again subdivide into the true capillaries. At their entrance into the hilus of the organ, the arteries receive a sheath from the capsule composed of fibrillar connective tissue, with numerous elastic fibres, and a moderate proportion of muscle-cells. Where the arteries are not more than 1-75th to 1-125th of an inch in diameter the sheaths become much looser and converted into a cytogenous tissue.—The *Capillaries*, bounded only by their every thin walls, pass in very direction through the spleen-pulp, penetrating the general mass of the organ and the interior of the Malpighian corpuscles. In their further course the walls of the capillaries frequently disappear, and the blood, in passing from the minutest arteries to

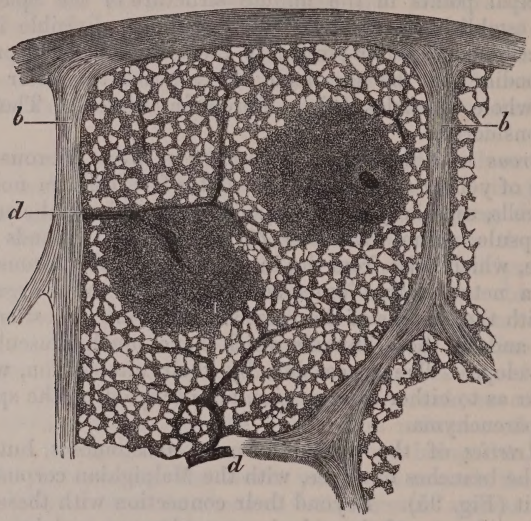
the minutest veins, moves in great part through *lacunæ*, or mere channels in the pulp tissue. The *Veins* receive their blood from these lacunæ, and form at first a kind of rete mirabile, or close plexus of anastomosing vessels, from which the larger veins that accompany the arteries arise. The veins are unprovided with valves.

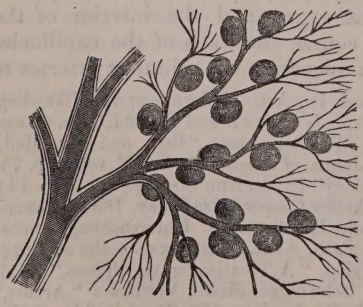
Fig. 94.



Section made at the periphery of the spleen in Man. At the upper part is the fibrous envelope sending off septa (*b*) into the interior of the organ. At its centre two Malpighian corpuscles are seen surrounded by the tissue of the pulp. The clear spaces correspond to the lacunæ of the serous network. *d*. Arterial ramifications.

III. The *Parenchyma* of the Spleen essentially consists of nuclei and cells in various stages of evolution, imbedded in a granular plasma (the periplast of Huxley); thus corresponding in every essential particular with the contents of the Peyerian glands (§ 153), and like them giving evidence of being in a state of rapid developmental change. Some of the nuclei are large and pale, and either spherical or flattened, others are smaller and elliptical. Kölliker and Klein have observed certain multinuclear flattened and branched cells, varying in size, and containing from four to ten or more nuclei; and similar bodies have been seen in the blood of the splenic vein. The peculiar *Splenic Corpuscles*, or 'Malpighian bodies of the Spleen,' are whitish spherical bodies, which may be regarded as lymph follicles. They are connected with the smaller arteries by short peduncles, like grapes with their fruit-stalks, or are sessile upon their sheaths (Figs. 94, 95). Their diameter usually varies between 1-3rd and 1-6th of a line; smaller bodies, however, are met with, which appear to be Malpighian corpuscles in an earlier stage of

Fig. 95.



Branch of *Splenic Artery*, the ramifications of which are studded with *Malpighian corpuscles*.

evolution. The boundary of each is an indistinctly-fibrous membrane, partly formed by the metamorphosis of the external cells of the contained parenchyma, and partly derived from the fibrous coat of the artery to which it is attached. Its contents correspond, in every essential particular, with the parenchyma in which it is imbedded. The walls are covered with a plexus of capillaries, and branches from these traverse the interior, as in the case of the Peyerian glands. The number and size of the Malpighian corpuscles bear a remarkable relation to the general state of nutrition; being greatest in healthy well-fed animals, diminishing in those that have been ill-fed, whilst in those that have been starved they disappear altogether. Hence their existence in the Human species has been denied; the opportunity of examining subjects not reduced by previous abstinence, being one that comparatively seldom occurs. There is no doubt, however, of their normal presence in the spleen of Man, as in that of other Mammalia.—Diffused amidst the parenchyma of the spleen, but in very variable amount, are both *coloured* and colourless cells, some of which are unchanged blood-corpuscles, whilst others appear to be transitional forms between leucocytes and red blood-cells.* Others, again, seem to be blood-discs in various stages of retrograde metamorphosis; these gradually diminishing in size, and assuming a golden-yellow, brownish-red, or even blackish colour, or having the pigmentary matter crystallized in a rod-like form in their interior; or, again, breaking-up into detached pigment-granules. The colourless corpuscles are probably only nucleated buds of the general matrix, and after separation are carried away in the blood-current as lymphoid corpuscles.† Occasionally (though very rarely in the Human subject) little

Fig. 96.

clusters of from 1 to 20 degenerating blood-corpuscles are found, included in a vesicular envelope.‡ Some of these bodies are seen in the blood of the Splenic vein; and it has been hence concluded that they do not constitute normal elements of the Splenic parenchyma, but that they are either contained in its capillaries, or, if actually diffused through the pulp, are so as

* On this point see Freyer, "Inaug. Dissert." Königsberg, 1874; and E. Neumann, "Archiv f. Heilkunde," Band xv. p. 441.

† Klein, "Quart. Journ. Mic. Science," vol. xv. p. 367.

‡ See Gulliver, "Lond. and Edin. Phil. Mag.," 1842, p. 169, Fig. 2.

a result of an abnormal extravasation. The course of the blood through the spleen appears to be, as stated by Mr. Gray and W. Müller, that the splenic blood, in its passage from the arteries to the veins, ordinarily escapes from the walled vessels into indefinite channels traversed by connective tissue, so that its corpuscles become diffused through the parenchyma without any departure from its regular course; and it is a confirmation of this view, that the amount of *coloured* corpuscles in the spleen-pulp augments with the general turgescence of the vascular system, and diminishes with the poverty of the blood, so that, in animals reduced by ill-feeding, it disappears altogether.

IV. The *Lymphatics* of the Spleen are few and inconsiderable in Man; being less numerous than in other glandular organs, such as the liver and kidneys. In some animals, as the horse,* they are more abundant, and form two systems, one of which may be followed into the interior of the organ accompanying the larger arteries and veins, and investing the smaller vessels with a distinct sheath, between which and the parietes of the blood-vessel numerous lymph-corpuscles may be found; whilst the other forms a plexus in the trabeculæ.†

V. The *Nerves* distributed to the spleen in the dog are of two kinds, centripetal and centrifugal. Section of a centripetal nerve and stimulation of its proximal cut-surface induces strong contraction of the spleen and pain, whilst stimulation of the distal extremity is without effect. Stimulation of the distal cut-surface of a divided centrifugal nerve iuduces local contraction of the spleen in the part corresponding to the distribution of the nerve. Section of a centripetal nerve alone induces no change, but section of a centrifugal nerve causes local swelling, the part becoming blue. When all the splenic nerves are divided the spleen swells.‡ When they are stimulated by induction shocks the spleen contracts and the liver swells, results attributed by some to the expression of white corpuscles from the spleen. The immediate centre of reflexion appears to be the left semilunar ganglion, stimulation of which produces very strong contraction; but since the reflex phenomena are greatly weakened or altogether abolished after section of the splanchnic nerves before their entrance into the cœliac ganglion, it is clear that the true reflex centres must be at a higher point than the semilunar ganglia, and Bulgak§ has demonstrated that they are situated in the spinal cord in the region of the first four cervical vertebræ, and are connected with the left semilunar ganglion by fibres running almost exclusively in the left great splanchnic nerve. Nerve fibres influencing the spleen are also found in the vagus.

VI. The *chemical composition* of the Spleen was found by Oidtmann to be—in 1000 parts, water, 750·31, solid residue, 249·69; of the latter, 242·32 parts were organic substances, and 7·37 inorganic. Amongst the organic substances albumin, fats, inosit, lactic, formic, succinic, acetic, butyric and uric acids, with sarkin, xanthin, leucin, pigment, and much cholesterin have been distinguished. The most remarkable circumstances respecting the inorganic constituents are the large relative quantity of soda salts, and of oxide of iron.‖ The pulp has an acid reaction. From the observations of Mr. Dobson,¶ which have been corroborated by other observers, it appears that the Spleen

attains its maximum volume at the time that the process of chymification is at an end—namely, about five hours after food is taken; and that it is small and contains little blood seven hours later, when no food has been taken in the interval. The removal of this organ from the body has been performed, even in man, without serious effects; whilst in some instances in animals perfect regeneration has occurred, which is probably attributable to the hypertrophy of the little splenculi so often present in the immediate vicinity of the Spleen;* in others, enlargement of the lymphatic glands in various parts of the body, as the neck and axillæ, has been observed. Maggiorani† noticed a deficiency in the amount of iron contained in the blood-corpuscles; and in the dogs operated on by Dr. Dalton‡ an unnatural appetite and a ferocity of disposition were exhibited, which may perhaps be attributed to imperfect assimilation of the food they consumed. It has been found§ that such mutilated animals endure starvation for an unusually long period of time, and that they eliminate more uric acid than in health.

159. The *development*‖ of the spleen in man occurs at the close of the second month of intra-uterine life. It is entirely derived from the mesoblast, and makes its appearance in the fold of membrane, named the mesogastrium, which connects the intestinal canal to the spine, in close relation with the pancreas. It consists at first of small cells, but vessels and fibres develope in it during the third month, and it soon becomes highly vascular. The Malpighian corpuscles are not formed till near the time of birth.—The pulp-tissue, at an early period of its formation, closely corresponds with that of the Supra-renal and Thyroid bodies in their earliest stages of evolution; consisting of nuclei, nucleated vesicles, and a fine granular plasma. Peculiar amœbiform cells or protoplasmic bodies appear to be constantly present in the embryonal spleen, and in the splenic-pulp, but their function is unknown.¶ When the splenic vessels are being formed, many of the above-mentioned nuclei are surrounded by a quantity of fine, dark, circularly-arranged granules; and these appear to develop into nucleated vesicles, of which, when the splenic vein is formed, nearly the whole pulp is composed; the nuclei subsequently break-up into a mass of granules, which fill the cavities of the vesicles. Thus, during fœtal life we have evidence of a process of cell-growth and maturation, followed by cell-destruction, in the colourless parenchyma. The largest proportional size and the greatest functional activity of the Spleen seem to be exhibited during adolescence and the most vigorous period of adult life, its proportionate weight to the whole body being then as 1: 320 or 400. Tarchanoff** finds that stimulation of the central end of a divided vagus with a moderately-strong interrupted current induces in the course of a few minutes persistent contraction of the spleen and augmented blood pressure; stimulation of the peripheral end had scarcely any appreciable effect. Stimulation of the central extremity of the sciatic induced contraction of the spleen and increased blood pressure, though to a less extent, probably through irritation of the vaso motor centre. Stimulation of the medulla oblongata induces extremely well-marked contraction of the spleen, which at the same

time changes its size and colour, these effects being only produced with uninjured splanchnics. The nerves of the spleen are large in Ruminants, but they contain much fibrous tissue.

160. The Adrenals (*Supra-Renal* bodies) in Man and most Mammalia present, like the kidneys, a division into cortical and medullary substances; the inner portion of the former having a remarkable dark-brown hue. The whole organ is invested by a fibrous envelope, from the inner surface of which processes are given off that dip into the cortical substance. The *cortical* substance has been divided by Arnold into three zones, named respectively the *Zona glomerulosa*, consisting of groups of cells imbedded in the meshes of a fibrous tissue; the *Zona fasciculata*, which forms the greater part of the cortex, and in which the groups of cells have a more columnar arrangement; and, lastly, the *Zona reticularis*, which is of a darker colour, and in which the columnar arrangement of cells is lost. The cells are everywhere polyhedral, finely granular, and frequently contain oil globules. The *medullary* substance is separated from the cortical by a layer of loose connective tissue, and is traversed in every direction by venous trunks. The stroma is delicate, and forms a reticulum, the meshes of which contain coarsely-granular cells. Some of these are branched. The supra-renal bodies are more highly supplied with nerves than any other gland-like structure in the body.* Kölliker counted no less than 33 branches proceeding to one of these bodies, derived from the sympathetic, pneumogastric, and phrenic nerves. These, after passing through the cortical, form a dense plexus in the medullary portion. In both parts, multicaudate ganglion cells are present. Holm, in the supra-renal bodies of oxen, found amongst other chemical constituents, inosit, with hypoxanthin, taurin, probably leucin, and an alkaline colouring matter.

attributable to hæmorrhage and the unavoidable injury to the nerves, and especially to the semilunar ganglia, attendant upon the operation, than, as Brown-Séquard believed, to the retention of some poisonous substance in the circulation, which it is the office of these bodies to remove. Since the year 1855 much importance has been attached to the study of the diseases of these organs, from the observation of Dr. Addison, that such cases are frequently associated with the deposition of pigment in the skin, causing it to assume a deep bronze colour. It has, however, been shown* that bronzing of the skin may be present and yet the supra-renal capsules be healthy; whilst cases† have been recorded in which disease was present in one or both of these organs, yet no bronzing of the skin occurred. Further inquiry is therefore requisite to determine whether the disease of the capsules and the discoloration of the skin really stand in the relation of cause and effect. According to Holm, a violet colour can be extracted from it, and Beaunis‡ states that it contains a peculiar organic substance which is reddened by iodine and rendered blue by iron perchloride.

162. In their *development* the Adrenals§ appear to be connected with the sympathetic ganglia.‖ They arise in the mesoblast before the seventh day of incubation, as two separate masses of blastema, situated between the upper end of the Wolffian bodies and the sides of the aorta; being totally independent (as concerns their development) of those bodies and of each other. The cortical and medullary portions have a distinct origin. From an early period their minute structure bears a close resemblance to that of the spleen, consisting of the same elements as that gland, excepting in the existence of more numerous dark granules, which give to the organ at a later period an opaque and darkly-granular texture; and their general history follows a very similar course: the Adrenals, however, acquiring their characteristic structure, and attaining their largest relative size, so early in fœtal life, as to surpass the Kidneys in dimension up to the tenth or twelfth week of Human embryonic development; though they afterwards diminish so much relatively to the Kidneys, as to possess in the adult condition only 1-28th part of their bulk.

163. The general structure of the *Thymus* Gland may be best understood from the simple form it presents, when it is first capable of being distinguished in the embryo. It is then solid,¶ but easily breaks down in the central part so as to form a single tube,** closed at *both* ends, and filled with granular matter; and its subsequent development consists in the growth of lateral shoots from this central axis. In its mature state it consists of an assemblage of glandular lobules, united together by connective tissue; and their cavities all communicate with a central mass, which some believe to be

p. 209; and Gratiolet, "Comptes Rendus," 1856. Dr. Creighton, in a paper read before the Royal Society in December, 1877, directs attention to the close histological similarity that exists between the cortical layer or zona glomerulosa of the Adrenals and those Graafian follicles, in which the ovum, after reaching a degree of ripeness, has shrivelled up and disappeared. The general intra-cortical mass he considers corresponds to another class of ovarian structures, the corpora lutea.

hollow (Figs. 98, 99). Each lobule is bounded externally by an indistinctly-fibrous membrane (Fig. 98, *a*), which sends prolongations (*b*) into its substance, that divide it into "acini" or gland-granules. Isolated gland-granules of the same kind are frequently to be met with on the main canal (Fig. 98, *c*).* The several follicles consist of a cortical and a

medullary portion, with a fine plexus of capillaries between them. The medullary parts of two neighbouring follicles are often united, so that this portion of the gland may perhaps be continuous throughout. Each follicle is composed of a reticulum of nucleated cells, and of cells. The reticular cells of the cortical portion have a disk-shaped nucleus nearly filling the cell, and give off long, fine-branching processes. The reticular cells of the medullary portion have one or two nuclei, present cell-bodies two or three times larger than the nucleus, and give off coarse, short processes. The medullary portion is also sometimes traversed by connective tissue trabeculæ. The free cells are of four kinds: small cells, resembling lymph-corpuscles; large granular cells of various sizes, many of which are attached by long processes to the trabeculæ and to the blood-vessels, and which contain one or two nuclei, and help to form (partly by a process of vacuolation) the concentric corpuscles of the thymus; giant cells, or multinuclear masses of protoplasm,† and

* See 'Note on the Minute Anatomy of the Thymus,' by Herbert Waling, "Proceed. Roy. Soc.," vol. xxvii. p. 369.

Times and Gaz.," 1863, vol. ii. p. 503; and Klein in Stricker's "Manual of Histology" (Syd. Soc. Transl.), vol. i. p. 365. M. Dahm's "Etudes sur la Thymus," Thèse, Paris, 1877. "Afanassieff. Archiv f. mik. Anat.," 1877.

Hassall's concentric corpuscles, which, as Ecker has pointed out, may be either simple or compound. The simple corpuscles are spheroidal vesicles with a concentrically striated investment, and either contain a homogeneous substance exhibiting fatty lustre, or present granular material and a nucleus in their interior. The compound corpuscles are much larger bodies, and consist of several simple vesicles enclosed by a concentrically striated common investment. Both forms become more numerous as the gland advances to complete maturity, and are believed by Mr. Watney to be concerned in the formation of the blood-vessels and trabeculæ. The granular cells, giant cells, and concentric corpuscles are almost entirely confined to the cortical portion of the follicles. The *blood-vessels*, the tunica adventitia of which is formed by the reticulum, are of small size. They run in lines from the periphery of the follicle to the edge of the medullary portion, which they enclose in a ring and then penetrate, presenting at the same time a larger size. In fresh specimens colourless nucleated cells are seen, which contain granules and spherules of Hæmoglobin, and are either parts of the concentric corpuscles or are in close connection with them (Fig. 100). Between the vessels and attached to them

Fig. 101.—Thymus-juice rich in corpuscles, with a few secondary molecules and the structureless minutely granular base.

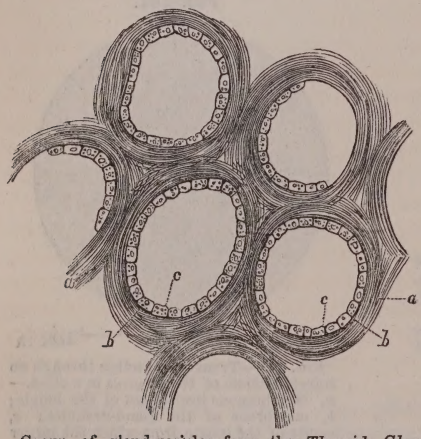
as well as to the connective tissue of the septa an exceedingly compact but very delicate network is extended, chiefly formed by the anastomosing branches of multipolar cells, in the interstices of which are numerous lymph-corpuscles; in addition a narrow meshed network may be observed, which is formed by the prolongations of the inter-follicular lymphatic vessels. The whole structure of the follicles resembles that of the Peyerian bodies.

164. The *lymphatics* of the interior of the follicles open into cavities lined by endothelium surrounding the follicles, which again communicate with elongated spaces imbedded in the trabeculæ and capsule of the gland. The chemical constituents of the *Thymus* are water, albumin, gelatin, sugar, fats, leucin, and sarkin, with xanthic, formic, acetic, succinic, and lactic acids, and the ordinary inorganic salts.* The expressed juice of the Thymus (Fig. 101)

* See Friedleben, in the "Journal de la Physiologie," 1859, p. 137; and v. Gorup-Besanez, "Phys. Chemie," 1862, p. 666.

in young and healthy animals possesses a creamy consistence and opacity due to the great abundance of corpuscles or free nuclei, identical in size, shape, and chemical characters with the corpuscles of the fluid of the lymphatic and mesenteric glands. The *nerves* are not very numerous, but were observed by Peremeschko partly to accompany the arteries, and in part to enter separately. Mr. Simon considers that they are mainly derived from the plexus which surrounds the first part of the subclavian artery, and which has its chief origin from the inferior and middle cervical ganglia. The greatest activity in the growth and development of this organ manifests itself, in the Human infant, soon after birth; and it is then, too, that its functional energy seems the highest. This rapid state of growth, however, soon subsides into one of less activity, which merely serves to keep up its proportion to the rest of the body; but its increase is continuous till the age of puberty is attained. From that time, during a variable number of years, it remains stationary in point of size; but, if the individual be adequately nourished, it gradually assumes the character of a mass of fat, by the development of the corpuscles of its interior into fat-cells, which secrete adipose matter for the blood. This change in its function is most remarkable in hybernating Mammals; in which the development of the organ continues, even in an increasing ratio, until the animal reaches adult age, when it includes a large quantity of fatty matter. The same is the case, generally speaking, among Reptiles.

Fig. 102.



Group of gland-vesicles from the *Thyroid Gland* of a child.—*a*, Connective tissue; *b*, membrane of the vesicles; *c*, epithelial cells.

165. The *Thyroid* body* differs from the other Vascular Glands in its elementary structures; for it essentially consists of an aggregation of vesicles† (Fig. 102, *b*, *b*), which seem to be furnished with a true limiting membrane, and therefore to be real gland-vesicles, imbedded in a stroma (*a*, *a*) of connective tissue, which supports a vast cavernous lymphatic network. The vesicles vary in diameter, in the Human subject from 1-2000th to 1-85th of an inch; and they contain an albuminoid plasma,‡ of either a faintly granular

* Good accounts of the Thyroid may be read in the following works:—Henle, "Handbuch der systematischen Anatomie des Menschen," 1866, vol. ii. pp. 535–541; Kölliker, "Handbuch der Gewebelehre," 5th edit., 1867, pp. 480–482; Verson, in Stricker's "Human and Comparative Histology" (Syd. Soc. Trans.), vol. i. pp. 370–372; Frey, "Das Mikroskop.," 4th edit., 1871, pp. 232 and 283; Baber, 'On the Lymphatics and Parenchyma of the Thyroid Gland of the Dog,' "Quart. Journ. Micros. Sci.," No. lxvii., for July, 1877, pp. 204–212, and "Philosoph. Trans.," 1876, vol. clxvi., part 2, p. 557 *et seqq*; Callender, "Proc. Roy. Soc.," vol. xvi. 1867, p. 25; Müller, "Jenaïsche Zeitschrift," 1871; Poincaré, "Journ. de l'Anat. et de la Physiol.," Sept. and Oct. 1875; Abstract in "Journ. of Anat. and Physiol." 1875, p. 451.

† These vesicles were formerly stated to be closed, but P. A. Boéchat ("Centralblatt," 1874, p. 84) has recently maintained, as the result of observations made upon healthy glands hardened in Picric Acid, subsequently placed in solution of gum, and finally in alcohol, that they intercommunicate freely.

‡ That the fluid does *not* contain true Albumin in solution, but some albuminous compounds, is indicated by the results of Dr. Beales's analysis ("Cyclop. of Anat. and Physiol.," vol. iv. p. 1106).

or of a somewhat oily aspect, which may be seen to exude from the epithelial cells (*c*, *c*) lining their interior. The vascular supply of the Thyroid body is extremely abundant; and, as in the preceding instances, the subdivisions of its arteries form a very minute capillary plexus upon the membrane of the vesicles. The *lymphatics* as described by Mr. Baber are very numerous, and are filled with a granular yellow material, which he supposes to be of a viscid consistence, and to be formed by a number of cells which may be termed parenchymatous; such cells originating in the inter-vesicular tissue external to the walls of the vesicles. The lymphatic spaces are lined by a layer of epithelium, which is often the only septum between the interior of the vesicles and the lymphatic spaces. The *nerves* are numerous, accompany the vessels, and are derived from the cervical parts of the sympathetic. They form close plexuses with interspersed ganglia.*—The Thyroid body originates on the third day in the Chick as an involution from the hypoblast of the throat opposite the point of origin of the second arterial arch. On the fourth day it forms a solid mass of cells, and on the fifth becoming independent of the epithelium of the throat, it presents a bilobed form, the two lateral masses being joined by a central portion or isthmus, with an outlying piece or pyramid of very variable form. The lateral lobes are situated on each side of the root of the neck, close to the separation of the carotid and subclavian vessels, and between the trachea and the branchial clefts, but quite independent, as far as regards their development, of either of those parts; their minute structure at an early period closely corresponds with that of the spleen and supra-renal glands. In Man the Thyroid body appears about the end of the second month of fœtal life, and then consists of tubes and vesicles, which subsequently become more and more defined, but no anastomoses have been observed.† Like the Supra-renal and Thymus, the Thyroid is of larger relative magnitude during intra-uterine existence and infancy than in after-life. The *Pituitary body* has the same essential structure as the vascular glands in general; presenting vesicles containing a finely-granular blastema with nuclear particles, imbedded in a fibrous stroma.‡ Two small glands, named respectively the *glandula intercarotica* and the *glandula coccygea* may be enumerated amongst the blood vascular glands. The coccygeal gland§ consists of one or several granules united by connective tissue into a mass about the size of a grain of hempseed, situated close to the ganglion impar. The arteries, derived from the median sacral, possess a very thick, circular, muscular coat, are tortuous, and dilate here and there into small sacculi; the nerves, from the ganglion coccygeum are numerous, and form plexuses with interspersed ganglionic cells. No lymphatics are known to be present. It is believed to be the remains of the vessels which correspond to the lateral branches of the aorta before the tail atrophied in the process of development. The inter-carotid gland resembles the coccygeal, but is of larger size; it contains a very large proportion of medullated nerve-fibres and ganglion cells. The vessels are convoluted and present sacculi; they are derived chiefly from the common carotid, and are believed to be the remains of the third branchial artery (Krause).

The recent researches of Neumann‖ and others seem to demonstrate that

the so-called "red marrow" occupying the cancellous tissue of the bones constitutes a kind of adenoid tissue in which lymph-corpuscles are developed. The vessels of this tissue are very numerous and large, and are connected by a delicate web of stellate cells, with long processes, the interstices of which are filled by a homogeneous mucin-like material. Imbedded in this are large numbers of cells, presenting every grade of development between lymph and fully-developed white and red blood-corpuscles. These must either gain entrance into the blood vascular system by penetrating the walls of the capillaries, or, as Hoyer thinks, the whole tissue resembles the lacunar system of the lymphatic glands, and the corpuscles are generated by fission of previously existing cells *within* the dilated and anastomosing capillaries. The large many-nucleated cells (myeloplaxes or giant cells) described by Robin as existing in the medulla of bones may possibly, as Neumann surmises, represent the mother-cells of the lymph-corpuscles, or as Bizzozero maintains, such many-nucleated cells with the pigment granules that are often found in them indicate that destruction as well as development of blood-corpuscles takes place in the medullary tissue of the bones. The whole subject has an important bearing on Leucæmia, which is so often associated with disease of osseous tissue. Mosler* observes that marked changes occur in the medulla of bones after extirpation of the spleen.

166. That the Ductless or Vascular Glands, of whose peculiar structure and relations we have thus taken a general survey, have some office of importance to perform in the preparation and maintenance of the blood, cannot any longer be reasonably questioned; and the determination of this point may be fairly regarded as a considerable step in the investigation. It is obvious, from the very copious supply of blood which they receive during the period of their functional vigour, and from the manner in which this is distributed by minute capillary plexuses, on the exterior, and even through the interior, of the glandular vesicles, that it must be subservient to some process of active change; and the aspect of the contents of these vesicles, as well as of the substance in which they are imbedded, indicates that cell-growth is rapidly proceeding, at the expense of the materials thus afforded.

The results of many recent investigations on these organs tend to show that they supply the germs of those cells which are ultimately to become blood-corpuscles. Such, it is well known, was the doctrine of Hewson† in regard to the Spleen and Thymus gland; and there are many facts which lend it a considerable probability. In the first place, we have seen (§ 158, II.) that there is no difficulty in the admission of such corpuscles into the smaller veins of the Spleen; and that there is no physical impossibility in the reception of particles of such a size into the interior of even a closed system of capillaries, is proved by the very curious fact already noticed in regard to the passage of starch-grains into the mesenteric veins (§ 142). Secondly, the spleen undergoes remarkable changes during the period of digestion, and under the influence of the nervous system becoming enlarged in volume with the increased activity of the circulation that takes place in the abdominal viscera soon after the ingestion of food, whilst it contracts when the upper part of the spinal cord and medulla oblongata are stimulated; circumstances suggesting the

† See his Third Series of "Experimental Inquiries," chaps. iii.–v.

idea that some material is stored up or that some process of growth occurs soon after food is ingested; the substances thus formed entering the vessels when the increased activity of the nervous system consequent on renewed supply of nutrient matter has induced contraction of the splenic musculature. Thirdly, the globular richness of the blood returning from the spleen is absolutely greater than that of the system generally, 1 c. mm. of splenic venous blood containing 5,352,500 red blood-corpuscles, whilst arterial blood generally contains only 5,092,500 corpuscles.* The red corpuscles, moreover, are small, spheroidal, resist the action of water for some time, and do not run into rouleaux, circumstances that favour the view of their recent formation.† Fourthly, if the spleen be extirpated, which has even been performed on man himself, showing that its functions are not indispensable for the preservation of life, the only effects observed have been increase in volume and pigmentation of the lymphatic glands,‡ probably in consequence of their taking on a vicarious action in the development of the white corpuscles. Fifthly, the period of greatest functional activity of these glands generally is during the state of early childhood, when the formative processes are going-on with extraordinary activity; and there is at this time a larger proportion of colourless corpuscles in the blood than at any subsequent period, at least in the healthy state. The relative proportion of the white to the red corpuscles in the splenic arterial and venous blood respectively seems to vary with the previous condition of the organ. Hirt found the proportion of the colourless to the coloured corpuscles to be as 1 : 2000 in the splenic artery, and as 1 : 70 in the splenic vein, but Tarchanoff and Swaen§ observed that the absolute number of white corpuscles is generally greater in arterial splenic than in venous splenic blood, the former containing, in one instance, 8200 white corpuscles in 1 c. mm., whilst the latter contains 7600 white corpuscles in the same bulk. In other instances the disproportion was still greater. A small relative proportion was in their experiments observed when the spleen was caused to enlarge by division of the splanchnic nerves,‖ and such diminution may be attributed either to mechanical arrest and accumulation of the white corpuscles in the spleen or to their destruction in this organ, or, lastly, to their conversion into red corpuscles. Further, as Prof. J. H. Bennett has pointed out, that peculiar condition of the blood, which consists in the multiplication of its colourless corpuscles, is almost always associated with hypertrophy of one or other of these bodies; and in one case of this kind, in which the Thyroid was the organ affected, its cells and their included nuclei were observed to be considerably smaller than usual, and the same peculiarity presented itself in the colourless corpuscles of the blood.¶ Hence there seems a strong probability that whilst the plasma of the blood is being elaborated by these bodies,

* Malassez and Picard, "Comptes Rendus," t. lxxix. p. 1511.

§ "Archives de Phys.," 1875, p. 324; and "Comptes Rendus," t. lxxx. p. 125.

‖ Bulgak found the maximum number of white corpuscles in the splenic venous blood when the organ was in its normal condition. These were fewer in the contracted and still fewer in the swollen condition, but if after being swollen the spleen was made to contract by stimulation of the nerves or otherwise, the number of white corpuscles underwent great increase.

¶ This fact is the more weighty, as, in another case observed by Prof. Bennett, the colourless corpuscles of the blood were of two distinct sizes, the smaller corresponding with the nuclei of the larger ones; and the *lymphatic glands* were found to be crowded with corpuscles also of two distinct sizes, exactly corresponding with those of the blood (see "Edin. Monthly Journal," October, 1851).

a constant supply of new blood-corpuscles is also afforded by them;* and that they thus effect for the nutrient materials directly absorbed into the Sanguiferous system that which the glandulæ in connection with the Absorbent system accomplish for the substances which *it* has taken up.†

CHAPTER VII.

OF THE BLOOD; ITS PHYSICAL CHARACTERS, ITS CHEMICAL COMPOSITION, AND ITS VITAL PROPERTIES.

1. *General Considerations:—Quantity of Blood.*

167. From the materials supplied in the Food, there is prepared, by the Digestive and Assimilative processes described in the preceding Chapters, that general nutritive liquid, the *Blood*, which, in the organism of Man (as in that of all the higher Animals) is constantly circulating through its vessels during the whole of life. From this liquid, each portion of the solid tissues has the power of extracting, and of appropriating to its own use, the particular components of its substance; these either pre-existing as such in the blood, or being capable of being readily formed from it by a process of chemical transformation. During its circulation, moreover, the blood draws into its current the effete particles which are set free by the disintegration of the tissues (probably at the very time when it gives-forth the components of the newly-forming structures), and conveys them to the various organs which are provided for their elimination. Hence the Blood not only contains the materials for the renovation of the tissues, but also the products of their decay: but there is an important difference in the proportion of these two sets of components; for whilst the former make-up the principal part of the mass of the fluid, the latter are only detectable in it with difficulty, so long as the excretory organs maintain their normal activity; and only make their presence obvious when they accumulate unduly, in consequence of the retardation or suspension of the eliminating operations.—But besides thus meeting the demand occasioned by the *constructive* operations, and preventing

* This view has been ably supported by Prof. J. H. Bennett, in "Edin. Monthly Journ.," March, 1852; and in his treatise on "Leucocythæmia."

† Some physiologists have arrived at the conclusion, from the modified forms of red blood-corpuscles observed in the splenic-pulp, from their enclosure in amœboid cells, and from the presence of yellowish granules composed entirely of iron oxide (Nasse, indeed, found that the splenic-pulp of old horses contained as much as 5 per cent. of iron, "Sitz-ber. d. Marburg Gesellschaft," 1875, No. 2), that the spleen is a place where the red corpuscles undergo disintegration. The blood corpuscle-holding cells appear to be very active white corpuscles which fasten upon and invest the red corpuscles, and division of the red corpuscles has been observed after they have been thus absorbed (Kusnezoff, "Wiener. Akad. Sitz-bericht,"1873, Band lxxvii., p. 58). The opposite process of the elimination of the fragments of broken-up red corpuscles from the white, has also been observed. (See, for experiments showing the activity of the splenic cells in taking up pigment particles, Ponfick, "Centralblatt. f. d. Med. Wiss.," 1874, p. 384.) A kind of relation appears to exist between the spleen and pancreas, for Schiff found that after ablation of the spleen the pancreatic juice loses its power of digesting albumin, and Herzen observed that whilst the pancreas of a fasting dog digested no albumin, and the pancreas and spleen together of a fasting dog digested no albumin, a mixture of the pancreas of a fasting dog with the spleen of a dog at the seventh hour of digestion, digested albumin freely ("Centralblatt f. d. Med. Wiss." 1877, p. 435).

the results of the *destructive* from exerting an injurious influence on the system, the Blood acts (so to speak) as the carrier of Oxygen introduced from the atmosphere, to the Muscular and Nervous tissues, to whose peculiar vital activity its presence appears to be an essential condition, the same element being also required in various other metamorphoses which form part both of the constructive and of the destructive operations; whilst conversely it imbibes the Carbonic acid, which is one of the chief products of the action of oxygen upon the tissues and fluids of the body, and conveys this to the lungs and skin for elimination.

168. From this variety in the operations to which the Blood is subservient, it naturally follows that the changes which it undergoes in different parts of its circulation are of a very diversified nature, and that the composition of the fluid in the several parts of its course will be far from uniform. Between the blood which is being distributed by the systemic Arteries to the body at large, and that which is being collected from it again by the systemic Veins, after having percolated the tissues, there is not only an obvious difference in hue, which indicates an important change, but there is also a considerable difference in composition, which is revealed by chemical analysis: and a difference of a converse nature presents itself, between the blood that is on its way to be distributed to the Lungs, and that which is returning from them. So again, although there is no obvious dissimilarity in physical characters between the blood which is transmitted to the Liver by the vena portæ, and that which is carried-off from it by the hepatic vein, yet chemical analysis reveals a very remarkable difference in their composition, and shows that the blood of the ascending vena cava (above the entrance of the hepatic vein), that of the right cavities of the heart, and that of the pulmonary artery, differs from all other blood in the body, in constantly containing an appreciable quantity of Glycogen, a peculiar substance readily convertible into sugar, which is formed in its passage through the Liver. In like manner the blood of the renal vein contains a smaller proportion of the chief component of the urinary secretion, urea,* than that of the renal artery; and in many other cases of blood returning from particular organs we know that important differences must exist, although they have not yet been detected by chemical analysis.—In the account to be presently given of the Blood, those most general characters and properties will be first described, which it presents in all parts of its circulation; the principal differences which have been substantiated in the composition of the blood in the several portions of its circuit, will then be noticed; and, lastly, a summary will be given of the most important of those pathological alterations which it exhibits in disease.

169. The quantity of Blood contained in the Human body is probably, for a man of average height, from 12 to 15 lbs.; but its precise determination is more difficult than might at first be supposed. The entire amount which flows from a large arterial trunk freely opened can by no means be taken as a measure; since, however readily it may be permitted to escape, a considerable quantity still remains within the blood-vessels, especially if the heart's action fail before the loss of blood has proceeded very far, so that it is not drawn from the venous system. A closer approximation may be made by opening several vessels at once,† and the proportion of the weight of the blood

* C. Bernard, "Leçons," 1859, vol. ii. p. 31; Picard, "Thèse sur l'Urée," 1856.

† The method adopted by Herbst, "De Sanguinis quantitate, qualis homini adulto et sano convenit." Goettingæ, 1822.

to that of the entire body is then found to be as 1 : 12 in the Ox, as 1 : 16 in the Dog, as 1 : 18 in the Horse, as 1 : 20 in the Goat, Calf, Lamb, and Hare, as 1 : 22 in the Sheep and Cat, and as 1 : 24 in the Rabbit. With these estimates the conclusions drawn by Vanner,* from observations made in the *abbatoirs* of Paris, pretty closely correspond; for he was led by them to the belief that, for horned cattle in general, the proportion does not vary far from 1 : 20. It is obvious, however, that no such method can give more than a *minimum;* since, even after the most complete exsanguination that the freest opening of the vessels can permit, a considerable quantity of blood is still retained in them, and especially in those of the head. Various other methods have been suggested, none of which, however, can be considered as yielding more than approximations to the truth. That of Vierordt† consists in multiplying the quantity of blood which is expelled from the left ventricle at each pulsation of the heart by the number of beats which occur whilst the blood performs one entire circuit of the body. He estimates the former (highly) at 6·3 ozs. av., and the latter at 27·7 beats; consequently the total quantity of blood is about 11 lbs. av., or between one-twelfth and one-thirteenth of the weight of the body. Welcker's method, termed also the "chromatic" or "colour" method, gives nearly the same result for Man and the Dog. It consists in first roughly estimating the quantity of blood in the animal by rapidly bleeding it to death. The portion that still remains in the small vessels is then removed by the injection of distilled water, or of a ·75 per cent. solution of common salt, and the whole body of the animal is finely minced and infused. These liquids are mingled, and on comparing their tint with a series of previously prepared "colour tests," the proportion of blood in which is accurately known, a practised eye may discern variations in the colour when the difference in the quantity of blood does not exceed 4 per cent. It is usual in such cases to administer carbon monoxide to the animal, since this gas, by its action on the red corpuscles, renders the blood of a uniform tint. Welcker estimates that a man weighing 143 lbs. has 11 lbs of blood. An interesting collection of cases has been brought together by Haller‡ of the amount of blood lost by hæmorrhage: and two remarkable instances are cited by Burdach,§ from Wrisberg, who states that a female who died from violent metrorrhagia had lost 26 lbs. of blood, and that 24 lbs. were collected from the body of a plethoric female who had suffered death by decapitation. In the first of these cases, it is probable that, as death could not have been *immediate*, some increase took place from the absorption of the fluids of the body; in the second, however, the suddenness of the discharge of blood, and its concurrence with the destruction of life, must have prevented any considerable augmentation from this source; and if any such increase did take place, it probably did not exceed the amount of blood remaining undischarged in the vessels. An important observation has been made by Bernard,‖ that the quantity of blood which can be obtained from a fasting animal is scarcely more than one-half of that contained in its vessels shortly after a full meal: a point to which no other observer appears to have paid attention, but which may account for some of the discrepancies observable in the different estimates¶. The blood

* "Comptes Rendus," tom. xxviii. p. 649. † "Physiologie," 1864, p. 138.

‖ "Leçons," 1859, t. i. p. 419.

¶ Valentin's method is founded on the diminution in the specific gravity of the blood after the injection of a known weight of water into the vessels, and gave for dogs the proportion of the weight of blood to that of body generally as 1 : 4½ ("Repert. f. Anat. und Phys.," Band iii.

is not equally distributed through the several organs and tissues of the body, but is most abundant as a rule in those which perform the most active functions; thus, the largest quantity is found in the liver, of which it forms about 28 per cent. In the spleen and kidney it is present to the amount of about 12 per cent.; in the brain and muscles there are about 5 or 6 parts per cent. by weight; in the bones two and a half per cent., and in the skin about 1 per cent. Worm Müller found that the injection of blood to the extent of 150 per cent. into the vessels of an animal proved fatal usually by rupture of the vessels. After such injection the blood corpuscles undergo regressive changes though more slowly, as estimated by the amount of urea eliminated, than when consumed as food, the process continuing as shown by the increase of urea in the urine for many days.

2. *Physical, Chemical, and Structural Characters of the Blood.*

170. The Blood as it flows-forth from an opening in a large vessel is an apparently homogeneous liquid, possessing a slight degree of viscidity, with a consistence and density somewhat greater than that of water, but especially distinguished by its *colour*, which is usually of a bright scarlet when it is drawn from an artery, and of a dark purple, sometimes almost approaching to black, when it is drawn from a vein. This difference of colour, however, is by no means constant; for arterial blood may sometimes be unusually dark, whilst venous blood is occasionally so florid that it might almost be taken for arterial. The former condition is observable when from any cause the respiratory process is imperfectly effected, as in the fœtus, and it may be especially noticed during operations performed under the influence of anæsthetic agents; it has also been remarked by Dr. John Davy, as usually characterizing the arterial blood of the inhabitants of hot climates,* and it occurs in blood that has been allowed to stagnate either in arteries or veins; but in any of these cases, the ordinary arterial hue is acquired by the blood when it has been sufficiently exposed to the air. The florid hue is presented by the venous blood of animals which are made to respire pure oxygen, and in those poisoned by CO; but it seems normal with some individuals whose respiration is peculiarly active. It is well marked in the blood returning from an actively secreting gland, and from a quiescent muscle.† When ordinary venous blood is examined in thin layers, it presents a deep red or purple tint by reflected light, but by transmitted light it assumes a greenish hue, thus presenting the phenomena of Dichroism; a peculiarity which is not possessed by arterial blood (Brücke): but when the gases of the

p. 281). Blake's method consisted in the injection of a definite quantity of some saline compound, as sulphate of alumina, and its subsequent quantitative determination, in a portion of blood drawn from another part of the system. This means of estimation gives the proportion of blood to that of the body as 1 : 8 or as 1 : 9 (see Prof. Dunglison's "Physiol," 8th edit. vol. i. p. 357), and is in accordance with the results obtained by Lehmann and Weber in their examinations of the quantity of blood discharged from two decapitated criminals (Lehmann, "Lehrbuch," 2nd edit. Band ii. p. 234). (See also Brozeit, Pflüger's "Archiv," 1870, p. 353; Steinberg idem, 1873, p. 101; and Gescheidlen, idem, 1873, p. 350.) Brozeit obtains the Hæmatin by means of ether and hydrochloric acid from a given quantity of the washings after venesection, compares it with that in the same quantity of blood, and makes the requisite calculation. Steinberg proceeds on the principle that solutions of hæmoglobin, when of a certain strength, transmit green light.

* "Anatomical and Physiological Researches," vol. ii. p. 140.—This fact, which harmonizes with the inference to be drawn from the observed results of a high external temperature in reducing the excretion of carbonic acid (CHAP. IX.), is of great practical importance.

† Bernard, "Leçons," 1859, vol. i. p. 324.

blood are wholly removed by exhaustion, both arterial and venous blood assume a deep black colour.* The refractive power of healthy blood on light is from 1·3546, to 1·3494; of serum, 1·3489.†—The *specific gravity* of the Blood is stated by Nasse‡ to vary (within the limits of health) between 1045 and 1075; the average being taken at 1055. The sp. gr. of the Corpuscles is about 1105, and that of the fluid in which they float about 1028. The *chemical reaction* of the blood is invariably alkaline, and very important purposes are served by this alkalinity. The *temperature* of the Blood, usually considered to be about 100° F., has been found to vary several degrees in different parts of the body.§ The blood which has the lowest temperature under ordinary circumstances is that which has circulated through the cutaneous capillaries where it has been exposed to the cooling influences of evaporation and radiation; Bernard, however, ascertained that on carefully enveloping the head or limbs of an animal in cotton wool, the temperature of the arterial and venous blood in the large vessels soon becomes equalized. The blood of the left ventricle again is, for similar reasons, having been transmitted through the pulmonary capillaries, generally‖ of a lower temperature than that of the right. The highest temperature is attained in passing through the glands, muscles, and nerves; for in all such parts, especially during the active performance of their functions, energetic processes of oxidation are being carried on. Hence the blood of the Vena Portæ and other viscera, which has traversed the capillaries of the intestines, spleen, &c., is warmer, especially during digestion, than even the arterial blood; and the blood which possesses the highest temperature in the body, and which is frequently 2° or 3° F. above the ordinary venous blood, is that of the Hepatic Vein, which has been subjected to the active assimilative operation of the liver. The specific heat of the blood of the Ox is on the average 1020.¶—When we add that the Blood has a saltish *taste*, and a faint *odour* resembling that of the pulmonary and cutaneous exhalations of the animal from which it is drawn, we have enumerated all the characteristics which can be made out by the unassisted senses.

171. When the Blood is examined with the Microscope, either immediately upon being drawn, or whilst it is yet circulating in the vessels of the living body (as in the tongue or foot of the Frog, the wing of the Bat, the omentum of the Guinea-Pig,** or any other membranous expansion of similar transparency), it is seen that its apparent homogeneity is not real, but that it consists of two very different components. These are a transparent and perfectly

‡ Wagner's "Handwörterbuch der Phys.," Art. 'Blut,' Band i. p. 82.

§ Bernard, "Leçons sur les Liquides de l'Organisme," 1859, iii. iv. v. vi.

‖ See the variable results obtained in Colin's experiments, recorded in the "Ann. d. Sci Nat.," Ser. v. t. vii. 1867, p. 83. Jacobson and Bernhardt found the temperature of the Left Heart to be from 0°·12 to 0°·42 Cent. warmer than the Right, as ascertained by the introduction of a compound needle connected with a thermometric apparatus through the parietes of the chest into the cavity of the ventricles (see "Centralblatt," 1868, p. 689). Körner, however ("Inaug. Dissert.," Breslau, 1871), and Heidenhain (Pflüger's "Archiv," Band iv. 558) support Bernhardt's statements. Albert and Stricker (Stricker's "Jahrbücher," 1873, p. 29) found a thermometer inserted into the *substance* of the muscular tissue of the left ventricle, stood 0°·5–0°·7 Cent. higher than when introduced into the *cavity* of the same ventricle in the living animal, which may in part explain the discrepancy in the different experiments. John Davy thought the blood in the left ventricle to be about 1° F. warmer than that of the right; but unless special precautions were taken to prevent loss of heat through the thin walls of the right ventricle, this is only what might be expected ("Researches Physiol. and Anatom.," 1839, vol. i. p. 149).

¶ Gamgee, "Journ. of Anat. and Physiol.," vol. ii. p. 139.

** See Burdon Sanderson, "Handbook for the Physiological Laboratory," 1873, p. 231.

colourless liquid which is known as the Plasma or *Liquor Sanguinis*, and a set of *Corpuscles* which are suspended in it:* these, when seen in mass, present a distinctly *red* hue, and it is to their presence alone that the colour of the blood is due; but there are also to be seen, scattered among the red, a few which are *colourless*, and which differ from the red in some other particulars presently to be noticed. If the recent observations of Dr. Norris, of Birmingham,† be substantiated, there are in addition a large number of transparent colourless cells, the presence of which can only be demonstrated by special methods of research. 100 vols. of human blood contain about 64 vols. of plasma, and 36 vols. of corpuscles.‡

172. The *Red Corpuscles* of the Blood (commonly, but erroneously, termed "globules") are minute, nearly transparent bodies of a flattened or discoidal form, which, in Man, as in most of the Mammalia, have a well-defined circular outline (Fig. 103, *b*). When isolated they appear of a yellowish-green tint, the red colour being only presented when there are several layers. The surfaces are somewhat concave; and there is a bright spot in the centre, which has been regarded by many as indicating the existence of a nucleus; though it is really nothing else than an effect of refraction, and may be exchanged for a dark one by slightly altering the focus of the Microscope (Fig. 103, *a* and *b*). The margin is sometimes crenulated. The *number* of the red corpuscles is about 4·5 millions in 1 c. mm. (or $\frac{1}{25}$th inch square) in women, and about 5 millions in men, with about 14,000 colourless corpuscles; upon which estimate there are about 250 thousand millions of red corpuscles in 10 lbs. of blood. The number of red corpuscles is greater in winter than in summer, in the country than in the town; under all circumstances causing diminution of the fluid part of the blood, as after the action of carthartics, and after moderate fasting. It is observed also to increase soon after eating, probably owing to a demand upon the fluid of the blood by the secreting organs. The globular richness is very high during the first day after birth, but it progressively diminishes in the course of the next ten days, since at this time there is a rapid growth of the child, with increase in the proportion of serum. The globular richness of the blood diminishes after long fasting, and the consumption of a large quantity of fluid, after want of sleep, and after sharp exercise.§ Vierordt observed a reduction in Marmots after long hybernation, from 7 millions to 2 millions in 1 c. mm. The number of corpuscles varies in different parts of the circulation, the largest number being contained in the small cutaneous veins, and a smaller proportion in the larger arteries and veins. It also varies with age.‖ Thus, from $2\frac{1}{2}$ to 15 years the red corpuscles vary from 2160000 to 5502000, the mean being 4269911. From 20 to 30 years they vary from 3399395 to 4899375, the mean being 4192687; and

from 30 to 55 years they vary from 3266250 to 5904375, the mean being 4080113. The mean of all Dubrisay's numerous observations was 4177109. Amongst animals the blood of the Carnivora contains more red corpuscles than that of the Herbivora. Malassez found 3·5 millions in 1 c. mm. in the rabbit; 18 millions in the goat; 10 millions in the camel; 2 to 3·3 millions in the cock; 700,000 to 2 millions in osseous fishes; 140,000 to 230,000 in cartilaginous fishes.* The richness of the blood is not, however, dependent alone on the number of the corpuscles, but upon their volume and the quantity of hæmoglobin they contain. The Corpuscles of Man and Mammalia seem to be homogeneous masses of germinal matter, soft, elastic, transparent, and structureless, refracting light singly, and having a specific gravity of about 1·105. The appearances of a proper cell-wall and nucleus which they present when subjected to the action of certain reagents† are probably deceptive, and arise either from physical or chemical changes occurring on their surface or in their substance. The average diameter of the red corpuscles is about 1-3200th of an inch (Gulliver), or 0·0077 mm. (Welcker), some, however, being as much as one-third larger and others one-third smaller than the average.‡ The thickness is about 1-12400th of an inch, or 0·0019 mm.§ The volume of each is estimated at 0·000000077217 of a cub. millimetre, the superficies at 0·000128 of a square mm., and the superficies presented by all the corpuscles together a square of 80 military steps to the side. The weight of a single corpuscle is estimated at 0·00008 mgrm.

The *form* of the Red Corpuscles is not unfrequently seen to change during their circulation; but this is generally in consequence of pressure, from the effects of which, however, their resiliency enables them to quickly recover themselves. In the capillary vessels they sometimes become suddenly elongated, twisted, or bent, through a narrowing of the channel; and this change may take place to such a degree as to enable the disc to pass through an aperture which appears very minute in proportion to its diameter. Great alteration in the form of the Red Corpuscles is effected by various reagents. Thus, if they be treated with water, they first become flat, and then double-convex, so that the central spot disappears; and by a continuance of the same process, they at last become globular, and so attenuated that a diffusion of their substance seems to take place through the surrounding liquid.‖

* In Malassez's method of numbering the corpuscles, the blood is drawn into a capillary glass tube of known capacity, diluted with a definite quantity of serum, and the corpuscles counted. See also Gower's 'Hæmatocytometer,' "Lancet," vol. ii. 1877, p. 799, and 1878, vol. ii. p. 901. (Cutler and Bradford, "Journal of Physiology," vol. i. p. 427, 1878–79, which last contains many references.)

† Dr. J. G. Richardson, of Philadelphia ("On the Cellular Structure of the Red Blood Corpuscle," Pamphlet, 1870), adduces arguments to show that the red corpuscles of the *Menobranchus*, or *Proteus* (*Batrachia*), are truly cellular. On division the contents escaped, and the cell-wall collapsed, and crystals were frequently found in the interior, over which the cell-wall appeared to be stretched like a tent over a tent-pole. Prof. Böttcher believes he has obtained evidence of the presence of a nucleus by treating blood with an alcoholic solution of corrosive sublimate ("Quart. Journ. of Mic. Sci.," 1877, p. 377. See also Hammond, "Month. Journ of Mic. Sci.," 1877, p. 147).

‡ Hayem, "Centralblatt," 1879, p. 366, describes small peculiar corpuscles, which he names "Hæmatoblasts," and believes to serve for the renovation of the red corpuscles.

§ The diameter of the corpuscles bears no constant relation to the size of the animal, even within the limits of the same Class; thus, although those of the Elephant (2, Fig. 105) are the largest among Mammalia (as far as is hitherto known), those of the Mouse tribe are far from being the smallest, being, in fact, more than three times the diameter of those of the Musk Deer (3, Fig. 105). There is, however, as Mr. Gulliver has remarked, a more uniform relation between the size of the animal and that of its blood-discs, when the comparison is made within the limits of the same Order.

‖ A large number of experiments of this kind were made, and their results accurately

With dilute solutions of common salt they become prickly on the surface, so as to resemble the fruit of the horse-chestnut (Fig. 104, *c*). The pro-

Fig. 104.

Various forms assumed by blood corpuscles after withdrawal from the body. The first represents an oval corpuscle of the frog breaking up into segments. The corpuscle marked *a* exhibits the formation of a crystal within a red corpuscle (Owsjannikow). *b*, *c*, *d*, forms represented by Böttcher. The remainder are from Mr. Gulliver's drawing.

jections, seen in profile, give the corpuscles a stellate form, and those seen *en face* appear as black dots. With acetic acid the corpuscles become globular and pale, but their outlines remain distinct; with solutions of magenta they swell up and assume a faint rose colour, a dark red spot appearing on some point of their circumference. With (2 per cent.) solutions of tannin,* after the lapse of twenty or thirty seconds some point of the circumference of the red corpuscle appears to give way and a small button of highly-refractile yellowish-green substance projects which sometimes contains a vesicular body that may again be retracted into the corpuscle by the action of acetic acid. The similar appearances produced by the action of a one per cent. solution of Boracic Acid on the red corpuscles of Reptilia have led Brücke† to regard the Blood corpuscles in these animals as consisting of a transparent shell or case, the '*œcoid*,' which is occupied by the '*zooid*,' the latter being composed of the nucleus and the hæmoglobin. If carbonic acid gas be transmitted through a drop of blood which has been mingled with a little saline solution so that the corpuscles have become horse-chestnut-shaped, the stellæ disappear, and although there are many which do not reassume their natural biconcave form, remaining saucer-shaped, yet their surfaces become smooth and even. On the transmission of air they again become horse-chestnut-shaped, and this alternating effect may be repeated several times. Klein‡ suggests that the action of tannin and boracic acid is due to phenomena of coagulation, and that of carbonic acid gas to the re-solution of a spontaneously coagulated constituent. Bile and Urea, according to Kühne, dissolve the red blood cells, though Jurasz§ maintains that they only swell up and burst; the addition of Urine seems to exert no other influence upon them

recorded, by Hewson (see his "Inquiry into the Properties of the Blood," 1782, and his "Description of the Red Particles of the Blood," 1788). See also the Lectures by Mr. Gulliver, delivered at the College of Surgeons in 1862–63, in *Med. Times and Gazette*.

§ "Inaug. Diss. Greifswald."

than a saline solution of equal density would do, as was long since ascertained by Hewson. Alkalies cause the corpuscles to swell and to become cup-shaped, after which they lose their colour and disappear. The passage of a current of electricity produced by the discharge of a Leyden jar (having a surface of 500 square centimetres) at intervals of from three to five minutes, causes the circular discs to become slightly crenate, then rosette-shaped and horse-chestnut-shaped; still later the processes are withdrawn and the corpuscles become round and pale, giving up their colouring matter to the surrounding fluid.* If blood be exposed to a temperature of 140° or 150° F., or if it be frozen and then thawed once or twice, or if the whole of the gases be removed by the air-pump, the corpuscles disappear, the colouring matter stains the serum of a lake colour, and only a few flocculi remain.† Professor Lehmann has remarked‡ that some of the red corpuscles resist the influence of reagents much more than others do, and he infers that the latter are the older cells as having the strongest tendency to disintegration. It is probable that the Blood-corpuscles, even whilst they are circulating in the living vessels, are liable to alterations of form from variations in the density of the fluid in which they float; and that such alterations may be constantly connected with certain disordered states of the system.§ Thus, even without such an alteration in the Blood as would constitute disease, its proportion of water may be temporarily so much diminished by diuresis or excessive perspiration, unbalanced by a corresponding ingestion of liquid, that the corpuscles may be made to present a granulated edge; which is rendered smooth again by the dilution of the liquor sanguinis with water. We hence see the necessity, in examining the Blood microscopically, of employing a fluid for its dilution that possesses as nearly as possible the same characters as the ordinary 'liquor sanguinis.' In the accompanying Fig. (105), which shows the form and size of the red blood-corpuscles of animals belonging to each division of the Vertebrate class, most accurately drawn to scale by Mr. Gulliver,‖ it will be seen that whilst in Man and all Mammalia they are destitute of a nucleus, or *apyrenæmatous*,¶ and with the exception of the Camel tribe circular (4), in Birds, Reptiles, and Fish, except only some of the lowest forms of the last, the corpuscles are uniformly oval and nucleated, or *pyrenæmatous;* in the Camel tribe, though the corpuscles are oval, yet they conform to the Mammalian type in being free from a nucleus, and in their small size. Mr. Gulliver has particularly insisted on this difference between the blood of the Mammalian and Oviparous Vertebrata, maintaining it to be the only single, universal, and characteristic difference between them.** In embryonic life, however, the red corpuscles even of Mammals possess a nucleus.

173. The Red Corpuscles, when freely floating in the liquor sanguinis of blood no longer in motion, exhibit a marked tendency to approximate one another; usually coming into contact by their flattened surfaces, so that a number of them thus aggregated presents the appearance of a pile of coins; or, if the stratum be too thin to permit them to lie in this manner, they partially overlap, or even adhere by their edges, which then frequently become polygonal instead of circular. The corpuscles when thus adherent, resist the

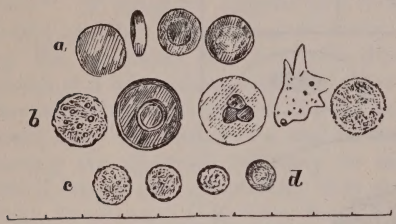
A Tabular summary of Mr. Gulliver's very numerous and accurate measurements of the

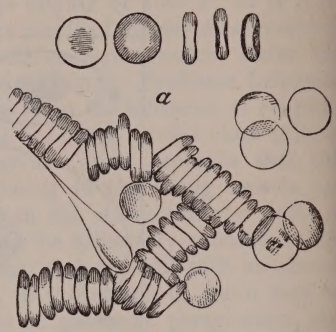
influence of forces which tend to detach them, and will even undergo considerable change of shape, rather than separate from each other; if forced asunder, however, they resume their normal form. After thus remaining adherent for a time, they seem to lose their attractive force; for they are then seen to separate from each other spontaneously. This peculiar tendency to aggregation is most strongly manifested in inflammatory blood, and assists by facilitating the descent of the corpuscles through the plasma in the production of the buffy coat. It has

Fig. 106.



Red corpuscles and pale cells of blood and lymph-globules. At *a*, four red corpuscles; *b*, five pale globules; *c*, *d*, four lymph-globules. The first pale globule at *b*, contains spherical granules, the last is only minutely granular, and the fourth is flattened and sending off processes: these three globules are in the natural state, but the second shows its circular nucleus exposed by the action of weak acetic acid, and the third the nucleus divided after treatment by stronger acid. Of the lymph-globules (which are from an inguinal gland) at *c*, the first two are in their natural state; and at *d*, the last two, after having been long steeped in strong acetic acid. From a child, aged three, accidentally killed.

Fig. 107.



Red corpuscles of *Man* (on the same scale of one-four-thousandth of an inch, as marked at Fig.105). At *a*, the corpuscles are seen flat on edge, and in rolls; the two first corpuscles show the central spot or concavity, dark and light: next are shown the biconcave and concavo-convex forms; among the rolls, one corpuscle is drawn out by virtue of its viscidity, and would resume its circular shape by virtue of its elasticity.

been regarded by some* as a purely physical phenomenon, on the ground that it can be imitated to a certain extent by partially immersing poised cork discs in water or other liquid, when the particles of the solid outside the liquid are found to have an attraction for each other, leading to movement through very sensible distances. But in the blood we have to deal with wholly submerged discs, and it is probable that a more correct explanation is that the corpuscles are rendered adhesive by the formation of fibrin between them, since if the chains be forcibly broken up, the separated corpuscles may often be seen to be still connected by fine threads, whilst various circumstances, such as the addition of salt, tending to promote, retard, or prevent the formation of fibrin, tend also to accelerate or prevent the appearance of rouleaux.† The proportion of the red corpuscles to the plasma or liquid in which they float is, in the horse, in 1000 parts, as 344·18 : 655·82, and in the pig as 436·8 : 563·2.‡ 1000 parts by weight of the moist red corpuscles of the dog contain water 569·3,

Red Corpuscles of the Blood of different animals, from all the classes and most of the orders of the Vertebrate series, is contained in the "Proceedings of the Zoological Society," No. cii., and also in his edition of the "Works of Hewson," already referred to, published by the Sydenham Society (p. 237). Manassein ("Centralblatt," 1871, p. 689) finds that agents or conditions which lower the temperature of the body, as Muriate of Quinine, Alcohol and Acute Anæmia, effect enlargement of the blood-corpuscles, whilst they are diminished in size by agents exalting the temperature of the body, as Heat, Septicæmic poisoning, and exposure to Carbonic Acid. They enlarge under exposure to Oxygen. Lastly, in certain diseases, as in pernicious Anæmia, they vary in size, many being far below the normal diameter.

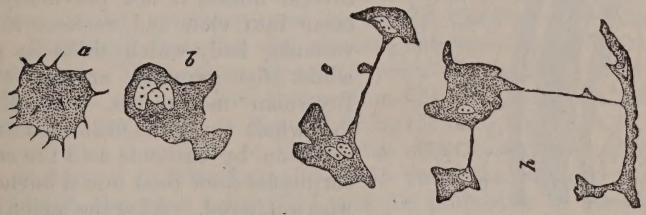
solids 430·70. Of the 430·70 parts of solids, hæmoglobin and albumin constitute 412·51 parts, cholesterin 1·26, lecithin 7·47, extractives 2·97, inorganic salts 6·49.*

174. Besides the red corpuscles of the blood there are others which possess no colour and may have an altogether different function. These are known as the *White or Colourless Corpuscles*, or not unfrequently Leucocytes (Fig. 108). They are identical with lymph- and pus-corpuscles, and when examined immediately after they have escaped from a blood-vessel are spherical and transparent, and vary considerably in size, the greater number being larger, but some being smaller than the coloured corpuscles, the average being about 1-2500th inch. The Colourless corpuscles possess a higher

Fig. 108.

Fig. 109.



Various forms assumed by the white corpuscles of the blood. The upper row represents the white corpuscles of Man; the lower row, white corpuscles from the Newt, showing changes effected in 15 minutes.

refractive power than the red; from which they are further distinguished by their greater firmness, their inferior elasticity, and lower specific gravity, their softly shaded and granular aspect, and the absence of any disposition to adhere to each other; so that, when a drop of fresh blood is placed between two strips of glass, and these are gently moved over one another, the white corpuscles may be at once recognised by their solitariness, in the midst of the rows and irregular masses formed by the aggregation of the red. This is still better seen in inflammatory blood, in which the Red Corpuscles have a peculiar tendency to adhere to one another, so that the distinctness of the White is more marked. They also differ from the red in their power of ingesting foreign particles and in their ubiquity, being formed in all the tissues both within and outside of the blood-vessels, and they have hence been termed migrating or wandering cells. They appear to be composed of protoplasm, and are destitute of an investing membrane. Under favourable circumstances, as when examined on a warm stage, they exhibit well-marked amœboid movements.† The mass of protoplasm of which each is formed presents a network of very fine contractile fibrils termed the "intra-cellular network," in the meshes of which a hyaline interstitial substance is contained. One or two nuclei, not always visible in the fresh and living condition, come into view

* Hoppe-Seyler and Hohlbeck, Hoppe-Seyler's "Physiol. Chemie," 1879, p. 402.

† Garrod suggests (*Times*, Jan. 23, 1878) that the amœboid movement may be growth in the direction of nutriment. See Preyer, Virchow's "Archiv," 1864, p. 417.

after removal from the body, which contain a similar network, termed the "intra-nuclear network," the fibres of which are in direct connection with those of the intra-cellular network.* Some of the characteristic changes of form are shown in Figs. 108 and 109. Colourless corpuscles may be readily distinguished in the blood circulating through the small vessels of the Frog's foot; and it is then observable that they occupy the quiescent layer, or exterior of the current, where the motion of the fluid is slow, whilst the *red* corpuscles move rapidly through the centre of the tube (Fig. 110). The colourless corpuscles, indeed, often show a disposition to adhere to the walls of the vessels; which is manifestly increased on the application of an irritant. In inflammatory states, or even when the circulation is merely checked in any part, the white corpuscles have a great tendency to escape through the vessels into the adjoining tissues or cavities of the body, and the term *diapedesis* is applied to the process by which they traverse the vascular walls. On the addition of distilled water the white corpuscles swell up, become globular, and cease to move; one or several nuclei, if not previously visible, come into view and coalesce to form a vesicular body which shifts its position, whilst the granules around it exhibit Brownian movements, and ultimately the whole corpuscle disintegrates. When acted on by carbonic acid the colourless corpuscles show their nuclei but are otherwise unaltered. After the action of acetic acid they present the appearance of globular bodies in which two, three, or more small shrunken nuclei are visible. In alkalies the colourless corpuscles swell and rapidly disappear, yet they exhibit remarkable resistance to the action of bile.† When excited electrically during their amœboid movements they assume the spheroidal form, but resume their activity on the cessation of the stimulus; after repeated excitation they expand and flatten, but still exhibit changes of form. Under the influence of successive shocks of greater intensity they swell, the granules exhibit molecular movements, and they finally disappear.‡ Quinine has a remarkable power of arresting the movements of the white corpuscles.§ The stroma of the white corpuscles contains a substance analogous to Myosin, with Lecithin, Cholesterin, Glycogen, and Fat. In addition to the alkaline albuminates and serum-albumin, the nucleus contains nuclein and lecithin.‖ Hoppe-Seyler finds

FIG. 110.

§ Binz, *Practitioner*, No. 51, 1872.

‖ See Hoppe-Seyler and Miescher in Hoppe-Seyler's "Med.-Chem. Untersuch.," Band iv. 1872, pp. 441 and 502, quoted in Brunton and Ferrier's 'Report on Physiology' in "Journ. of Anat. and Phys.," vol. vi. p. 450. Also Brunton's paper on the Chemical Comp. of the Nuclei of Blood Corpuscles in "Journ. of Anat. and Phys.," vol. iv. 1870, p. 91. The distinctive chemical characters of 'nuclein' appear to constitute an answer to Mr. Savory's view that "the existence of a nucleus in the red corpuscles of Ovipara is due to changes after death or removal from the vessels. See his paper in "Month. Micr. Journ." 1869, vol. i. p. 235.

that the white corpuscles only contain glycogen as long as they exhibit movements, and that when they become rigid they lose their glycogen and contain sugar. The white corpuscles of the blood, both of the frog and triton, as well as those of man, have been observed by Klein to multiply by fission ;* but they are essentially regenerated from lymph corpuscles of lymphatic glands and from certain endothelial cells of the serous membranes.

The proportion which the white or colourless corpuscles bear to the red, is very small in the blood of man and the higher Vertebrata ; being, in the state of health, according to the estimate of Moleschott (which is confirmed by Kölliker),† not more than 2·55 to 1000. Some discrepancy exists in the statements made by competent observers in regard to the influence of food. Thus, according to Hirt, of Zittau,‡ in the morning before breakfast the proportion is one colourless to 716 coloured corpuscles ; half an hour after breakfast 1 : 347 ; between two and three hours after breakfast 1 : 1514 ; ten minutes after dinner 1 : 1592 ; half an hour after dinner 1 : 429 ; two hours and a half to four hours after dinner 1 : 1481; half an hour after supper 1 : 544 ; and between two and a half to three and a half hours after supper 1 : 1227. Cutler and Bradford,§ however, observed an increase in the globular richness of the white corpuscles during a fast, and a decrease after a meal. The white corpuscles are more abundant in children than in adults, and there is an increase during pregnancy and in certain diseased conditions of the system. Dubrisay‖ finds that the absolute number of the white corpuscles varies with age. Thus, from 2½ to 15 years the number of white corpuscles in 1 cub. mm. of blood varies from 761 to 12,181, the mean being 6704, and the proportion to the red being 1 : 648; from 20 to 30 years the number varies from 2284 to 11,306, the mean being 6113, and the proportion to the red 1 : 700; from 30 to 55 years the number varies from 2512 to 14,465, the mean being 6931, and the proportion to the red 1 : 616. The mean of all observations, which were very numerous, gave 6307 white corpuscles in 1 cub. mm. of blood, and the proportion to the red 1 : 683. In the oviparous Vertebrata the proportion is higher ; thus, it has been observed by Wagner¶ to be as 1 : 16 in the blood of a frog examined in February, and as 1 : 6 in similar blood examined in August. In one vertebrated animal, the *Amphioxus*, the red corpuscles are wanting altogether ; their place in the circulating blood being taken by the colourless. And in the invertebrate series generally, the corpuscles of the circulating fluid correspond rather to the *colourless* corpuscles of the blood of Vertebrata, and to the corpuscles of lymph and chyle (which may be regarded as the same bodies in an earlier stage of development), than they do to the *red* corpuscles, which are peculiar to Vertebrata.** Thus, in one of its most characteristic features, the blood of Invertebrata†† (and of Amphioxus) may be likened rather to the lymph and chyle of vertebrated animals than to their blood ; and this resemblance is strengthened by the fact that there is no distinction in the former between the

†† Except in a few cases, such as Solen, Siliqua, Sipunculus, and in the common earthworm, in which the corpuscles appear to be truly respiratory in function.

absorbent and the *sanguiferous* vessels, which in the latter respectively contain the nutritious fluid in its earlier and in its later stages of development. Moreover, the earliest blood-corpuscles of the embryo of even the highest Vertebrata are colourless; and long after the blood has acquired its characteristic hue from the development of red corpuscles, the colourless corpuscles bear a very large proportion to the red, so as even to equal them in number (as the author is informed by Mr. Gulliver), in the blood of fœtal deer an inch and a half long, and absolutely to preponderate in the blood of still smaller embryos.

175. Dr. Norris, examining the blood in extremely thin layers* observed that the red corpuscles as they moved in the plasma often presented indented outlines, apparently in consequence of these impinging against some unseen circular bodies. Further research has led him to conclude that the blood contains a large number of transparent corpuscles of the size of the red discs, which, under ordinary circumstances, are invisible, because their refractive index and colour coincide with those of the plasma. The outlines of these transparent corpuscles are best brought into view by altering the refractive index of the plasma, as by pricking the finger through a minute drop of a saturated solution of common salt and permitting the fluid to run between the closely approximated surfaces of the glass. Dr. Norris finds that by taking advantage of the tendency of these corpuscles to adhere to solids, they may be withdrawn from the plasma, and if at the moment of isolation the adherent groups are exposed to the vapour of osmic acid, especially at a temp. of 0° C., the form of the corpuscles is preserved and they are found to be colourless biconcave dics. The corpuscles may be stained whilst still contained in the plasma by the addition of a strong solution of carmine in an ammoniated and saturated solution of common salt. They then first appear as delicate white discs, floating in the coloured fluid and contrasting strongly with the red discs, but soon disappear by assuming the same tint as the stained plasma; finally, they reappear, having acquired a deeper tint than the surrounding fluid. In investigating the *source* of these colourless transparent biconcave discs, between which and the red discs corpuscles of every gradation of colour may be seen, Dr. Norris observed that the morphological elements of the spleen and lymphatic glands are liable to considerable changes, both of size and form, and that when examined with due precaution the lymph-corpuscles appear as discs of the same diameter as the red corpuscles, with depressions on the surface, giving them a granular aspect, and representing, as he believes, the commencement of the process by which the disc is rendered biconcave. They then enter the blood and become invisible, in consequence of their having the same colour and refractive index as the blood plasma, remaining in this state till they have acquired sufficient colour to contrast slightly with this liquid, when they reappear as pale ordinary red corpuscles, before which period their biconcave form is perfected.

176. If the blood of a Mammal be exposed drop by drop to a cold of 8° or 9° Fahr., and then be rapidly warmed to 68° Fahr., the corpuscles will be found to have lost their colour, whilst the serum is deeply stained. A kind of analysis of the constituents of the blood may thus be effected. To the material of the corpuscles, which retain for some time their original form and elasticity, though devoid of colour, the term *Stroma* has been applied,

* The blood was allowed to occupy the space between a flat slide and a slightly convex cover glass strapped firmly down upon the slide, so as to exhibit Newton's rings, the two glasses being less, therefore, than 1–10,000th of an inch apart, and the corpuscles being examined on the flat surface and in single layer. (Demonstration given by Dr. Norris at Cork Meeting, Brit. Med. Assoc. 1879.)

whilst the colouring matter has been named *Oxyhæmoglobin*, Hæmatoglobulin, or Hæmatocrystallin, and is characterized by its property of assuming under favourable circumstances the crystalline form. The *stroma* appears from its reactions to be chiefly composed of *albuminous compounds*, the nature of which has not been clearly ascertained, together with *lecithin*, *cholesterin*, and salts. The colouring matter of the blood, which forms 12 to 15 per cent. of the total mass of the blood, or from 86 to 94 per cent. of the organic constituents of the red corpuscles, appears to exist in two states, Hæmoglobin and Oxyhæmoglobin. Both are contained in venous blood, but only the latter in arterial, the affinity of Hæmoglobin for oxygen being so great, that in traversing the capillaries of the Lungs, where it is brought into relation with air, it absorbs oxygen, and is immediately converted into Oxyhæmoglobin, becoming at the same time much brighter in colour. On the other hand, in traversing the systemic capillaries a portion of the Oxyhæmoglobin loses its oxygen and becomes converted into Hæmoglobin, which is of a darker hue. The difference in colour between arterial and venous blood is in great measure attributable to this chemical change. Hoppe-Seyler has suggested the use of the terms Arterin and Phlebin for the oxidised and reduced Hæmoglobin respectively, and Stokes has named them scarlet and purple Cruorin. *Oxyhæmoglobin* may be obtained by mixing freshly-drawn blood with common salt, and thus allowing the corpuscles to sink. The plasma is decanted, and a little ice-cold water added. The mass is agitated with cold ether, which is poured off, and the dark-red watery solution is filtered quickly, mixed with a quarter of its volume of cold alcohol, and allowed to stand for several hours at a temp. of about 20° F. The crystalline mass is placed on a filter and pressed, then quickly dissolved in a little water at 70° F.; on cooling to 32° F. precipitation with ice-cold alcohol, and putting aside at temp. below 32°, crystallization can be effected.* Oxyhæmoglobin is very unstable; it undergoes decomposition even in being desiccated, and a fibrin-like body, a substance resembling serum-albumin, and a colouring matter are produced, which last resembles Hæmatin in acid solution in its spectrum, whilst it differs from it in being soluble in water and in dilute acids. All acids act upon solution of Oxyhæmoglobin, even at a temperature of 40° F. The bright-red solution becomes dark-red or brown, and it no longer presents dichroism. In this decomposition albumin is separated, which if it remain in solution is Syntonin, and a new colouring matter is formed, which, according to the nature and strength of the acid, may either contain albumin, and is then named Methæmoglobin, or be free from albumin, in which case it is Hæmatin. Oxyhæmoglobin dissolves readily and without change in very dilute alkaline solutions

* In some instances it is only requisite to dilute the blood and allow one or two drops to dry spontaneously. In others, an abundant crop may be obtained by transmitting air free from carbonic acid through the blood for several hours; or the blood after being defibrinated may be frozen (Rollett's plan) and allowed slowly to thaw; or (Böttcher's method) a considerable quantity of cold water may be injected into the veins of the animal whilst it is being killed by chloroform inhalation, the blood removed rom the heart mixed with its own volume of cold water and some alcohol added, when the whole mass changes into a crystalline pap; or (Kühne's and Thiry's plan) the blood left after the formation of a clot is mingled with some 0·5 per cent. aqueous solution of crystallized ox-bile (tauro- and glycocholate of soda) and then with alcohol (90 per cent.) containing a little acetic acid. The method given by Preyer as the best adapted for microscopical investigation is that to a small quantity of blood free from fibrin, sufficient water should be added to give a clear solution; if on evaporation in the cold a drop of the solution covered by a thin slip of glass give no crystals, about a quarter of its volume of alcohol must be added and the fluid placed in a freezing mixture: crystals will in almost all instances be immediately formed. Speaking generally, in order to obtain blood crystals, the corpuscles must be dissolved, and the colouring matter thrown down by alcohol, or by some salt or acid.

at a low temperature, but strong solutions, or even weak solutions at a moderate or high temperature, effect its decomposition. The solution becomes green in thin layers, brown and dichroic in thick layers, and its spectrum changes. Oxyhæmoglobin readily yields its oxygen to powerful reducing agents, but it is incapable of oxidizing grape-sugar, uric acid, or fat. It possesses in a high degree the power of converting oxygen into Ozone. Hæmoglobin—*i.e.*, reduced oxyhæmoglobin, is much more soluble in water than oxyhæmoglobin, and crystallizes with difficulty or not at all. Professor Ray Lankester* has shown that oxyhæmoglobin is present in the *plasma* of the vascular fluid of various Invertebrata as in that of the Annelids Lumbricus, Eunice sanguinea and Hirudo, in that of the crustacean phyllopod, Cheirocephalus diaphanus; in that of Chironomus amongst Insecta and the Planorbis amongst Mollusca.

177. Oxyhæmoglobin crystals are obtained with the greatest facility from

the blood of the dog, cat, horse, rat, guinea-pig, squirrel, and goose, less easily from the blood of man, and with the greatest difficulty from the mouse, the mole, and the bat.† Some of the chief forms of oxyhæmoglobin crystals are exhibited in the Figs. 111, 112. It has been ascertained that with the exception of those of the squirrel, which are hexagonal, the crystals of the blood of other animals belong to the rhombic system. Those of man present the form of elongated rectangles, rhombs, and four-sided prisms, with dihedral summits. The crystals of the blood of the rabbit are very similar to those of man. Those of the dog are long four-sided needles, terminated by one plane surface. From cat's blood similar crystals may be obtained, together with thin rhombic and six-sided plates. In the guinea-pig tetrahedra, and in the rat tetrahedra and octahedra are found. Oxyhæmoglobin crystals from whatever animal they may be obtained are always perfectly transparent, and doubly refracting with silky lustre; the crystals of reduced hæmoglobin are pleochromatic, alternating from red or purple to green; but those of oxyhæmoglobin are not so, presenting the colour of the blood from which they are got. When fresh they are soft and highly elastic, breaking with an uneven splintery fracture; exposed to the action of water they imbibe it and undergo various changes of form, never, however, assuming that of a red blood-corpuscle. They contain from 3 to 9 per cent. of water of crystallization. The sp. gr. of oxyhæmoglobin probably varies from 1·3 to 1·4. All the varieties are soluble in

† Hoppe-Seyler, "Med.-Chem. Untersuch.," 1867, p. 174.

water, and the solubility increases with the temperature. They are insoluble in absolute alcohol, ether, in volatile and fixed oils, benzol, turpentine, chloroform, and carbon disulphide. They dissolve readily and for some time without undergoing decomposition in the alkalies and most alkaline salts (carbonates, phosphates, borates), but in a few days the solution becomes cloudy from decomposition. Solutions of most acids quickly dissolve them, but decomposition sets in in the course of a few hours. They remain long unchanged in healthy urine, in saccharine solutions, in bile, and serous transudates. Hæmoglobin, though a crystalline compound, is scarcely diffusible, and when pure is not fibrino-plastic. The per-centage composition of hæmoglobin obtained from the dog is C 53·85, H 7·32, N 16·17, Fe 0·43, S 0·39, O 21·84. The amount of oxygen that is taken up by one gramme (15·432 grains) of Hæmoglobin is 1·16 c.c.*

178. *Methæmoglobin* results from the action of any oxidizing substance on oxyhæmoglobin. It is intermediate, in regard to the amount of oxygen it contains, between Hæmoglobin and Oxyhæmoglobin. It is found in old extravasations of blood, and in the blood after the respiration of Amyl-nitrite, and even in the red blood-corpuscles of the living animal.† It is amorphous, very easily soluble in water, insoluble in alcohol and ether. It is converted by acids and alkalies in the absence of oxygen into albumin and hæmatin, and by reducing substances in neutral or weakly alkaline solutions into Hæmoglobin. Its spectroscopic characters are shown in Fig. 115, No. 5.

Hæmatin is obtained by acting on red blood-corpuscles with alcohol containing a little sulphuric acid at a gentle heat; the blackish brown solution obtained owes its colour to hæmatin. It may also be obtained by the extraction of dried and powdered red corpuscles with glacial acetic acid and a little sodium and chloride. Teichmann's *Hæmin* crystals are thus obtained, which have the formula $C_{68}H_{70}N_8Fe_2O_{10}2HCl$. These crystals can be obtained from a very minute speck of blood. They form minute rhombic tablets (Fig. 113), or stellæ of red, brown, or black colour, becoming violet on exposure to oxygen, and losing their transparency on exposure to carbonic acid. They dissolve easily in alkaline solutions, and then on the addition of an acid give a flocculent brown precipitate of hæmatin, $C_{68}H_{70}N_8Fe_2O_{10}$. Hæmatin is insoluble in water, alcohol, ether, and dilute acids, but readily soluble in alkaline solutions. Both acid and alkaline solutions absorb red light up to the line B. They show an absorption band between C and D, and somewhat nearer the former, and a very faint broad band between D and F. Hæmatin withstands without decomposition a temperature of 350° F., but above that point carbonizes.

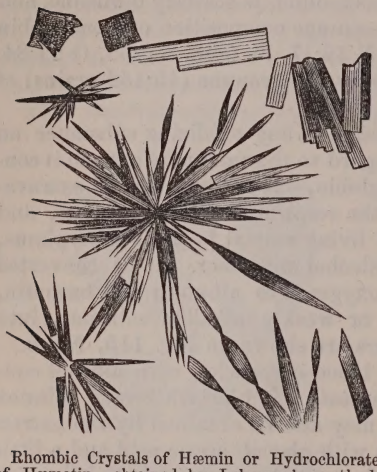
Hæmochromogen, or *reduced Hæmatin.*—This substance was obtained by Stokes by treating solutions of hæmatin with alkaline reducing agents, and it may also be produced by the action of alkalies or acids, or of alcohol, or of a

* G. Hufner, "Zeits. f. Chemie.," 1877, Band i. p. 317. Hoppe-Seyler estimates it theoretically at 1·67 c.c. at 0° C., and 760 m. ("Physiol. Chemie.," 1879, p. 380). Dybkowsky, proceeding on the principle of replacement by CO, found it to be 1·18 c.c. (Hoppe-Seyler, "Med.-Chem. Unters.," Band i. 1866, p. 117). Preyer obtained the numbers 1·37, 1·31, and 1·23 c.c. ("De Hæmoglobino Observat. Diss." Bonn, 1866, p. 19). Strassburg estimated it at 0·885 c.c. (Pflüger's "Archiv," Band iv. p. 454.)

† Hoppe-Seyler, "Phys. Chem.," 1879, p. 391.

temperature of 100° C. in the absence of oxygen on solutions of hæmoglobin.* Hæmochromogen has so powerful an affinity for oxygen that it has not been isolated. Its alkaline solution exposed to oxygen is converted into hæmatin, its colour at the same time undergoing considerable change. Acid hæmochromogen absorbs red and orange, at least as far as the line D, and violet and blue to G. There is an absorption line between D and E, and another at E, which is fainter, and disappears on dilution.

Fig. 114.



Rhombic Crystals of Hæmin or Hydrochlorate of Hæmatin, obtained by Lehmann's method. They are obtained when blood is subjected to the action of a mixture of one part of alcohol, 4 parts of ether, and 1-16th of oxalic acid, and appear as thin brownish and brownish-green, striated, transparent crystalline laminæ, often curiously twisted upon their long axes, and soon spontaneously changing into flat rhombic octahedra.

Hæmatoporphyrin. — The iron-free hæmatin obtained by the action of concentrated sulphuric acid upon hæmatin consists essentially of Hæmatoporphyrin mingled with a substance named *hæmatolin*, which is insoluble in most menstrua, and has a composition expressed by the formula $C_{68}H_{78}N_8O_7$.† Hæmatoporphyrin is soluble in alkaline solutions, and has the composition $C_{68}H_{74}N_8O_{12}$. Its acid solutions present a narrow and feeble absorption band just before the line D, and a darker and broader one between D and E. The alkaline solutions which, like the acid, have a fine purplish hue, exhibit four absorption bands: a narrow one between C and D; a broad and dark one at D, stretching farther towards E than toward C; a narrow, feeble one between D and E, but nearer E; and, lastly, a broad dark one commencing before *b* and extending beyond the middle of the interspace between *b* and F. Considerable interest attaches to this body since it closely resembles hydrobilirubin in its spectrum and in its relation to solvents. When treated with concentrated sulphuric acid, the iron can be wholly withdrawn, and the hæmatoin, or *iron-free hæmatin*, called also *acid-hæmatin*, thus obtained, so far differs from ordinary hæmatin, that whilst it is insoluble in dilute acids, it presents the important chemical feature of being polymeric with bilirubin, or the colouring matter of bile, as shown by the following formulæ:—

$$\underset{\text{Hæmatoin.}}{C_{96}H_{51}N_6Fe_2O_{18}} + 3H_2O = 3(\underset{\text{Bilirubin.}}{C_{32}H_{18}N_2O_6}) + 3FeO$$

Thus, Hæmatin is the substance which contains all the iron of the blood, whilst the Hæmatoin (which, according to Hoppe-Seyler, consists of hæmatoporphyrin and hæmatolin) contains no iron. The *Hæmatoidin* crystals observed by Virchow, and stated by him to occur in blood that has long been extravasated, as in old apoplectic clots, and in corpora lutea, appear to be identical with bilirubin, or the colouring matter of bile. The formation of these crystals takes place with considerable rapidity. If a little coagulated pigeon's blood be introduced beneath the skin of that bird, hæmatoidin crystals appear in the course of two days.‡ The crystals are soluble in ammonia, inso-

luble in alcohol and acetic acid. They are acicular, frequently bent, partly grouped into stellæ and doubly refractile. They are insoluble in alcohol, ether, and water; but very soluble in weak solution of potash, or weak acetic acid.*

179. Spectrum Analysis of the Blood.—The researches of Brewster, Herschel, and Müller showed that when solutions of various colouring matters are placed in the solar spectrum, certain portions of the light are absorbed, and dark striæ or bands appear in the spectrum corresponding to those rays that have been arrested. F. Hoppe† found that in a very diluted mixture of blood and water the spectrum exhibited two well-marked dark striæ (2, Fig. 115) in the yellow and in the green, both lying between the Fraunhofer lines, D and E. When less dilute, the two lines blended together, and with increasing concentration, the violet and blue, as well as the green and yellow, gradually vanished, till at length only the red remained. Arterial and venous blood alike showed the two striæ, as did also dried blood, and blood treated with CO_2,CO,H,SH,NH_3, &c.; but the striæ rapidly disappeared when acetic or tartaric acid, or caustic alkaline lyes were added to the blood. He further found that the ordinary absorption striæ were rendered most distinct by precipitating a mixture of blood and water with acetate of lead, and throwing down the lead with carbonate of soda. Prof. Stokes,‡ on repeating the experiments of Hoppe, confirmed them, and at once proceeded to inquire whether it were possible to imitate the change of colour of arterial into that of venous blood, on the supposition that it arose from reduction. This he accomplished by adding solution of protosulphate of iron, with enough tartaric acid to prevent precipitation by alkalies, to the blood, when the colour of the solution immediately became much deeper, and the two absorption bands were at once replaced by a single band (4, Fig. 115) shaded off at the borders, and occupying an intermediate position between them. On exposure to air, the bands originally present reappeared. Hence he inferred that the colouring matter of the blood, like indigo, is capable of existing in two states of oxidation, distinguishable by a difference of colour and a fundamental difference in the action on the spectrum. To this colouring-matter he has applied the term Cruorin, suggested by Dr. Sharpey—its two states of oxidation being termed scarlet cruorin, and purple cruorin respectively. Prof. Stokes showed also that hæmatin, which is the result of the action of weak acids on cruorin, was similarly capable of oxidation and reduction, and that it shows well-defined and highly-characteristic lines, which, however, are by no means identical with those of cruorin. Prof. Stokes suggests, as a physiological deduction from his experiments, that cruorin is to be regarded as the carrier of oxygen to the tissues, since it absorbs that gas with extreme facility; whilst under the influence of reducing agents it permits it again to be withdrawn from it. Both Hoppe and Stokes refer to the applicability of spectrum analysis for the detection of blood-stains in medico-

by transmitting light through two Nicol's prisms and an intervening plate of quartz or selenite, with its axis at 45° to the plane of polarization. The number of the dark bands due to the interference of the luminous waves may be regulated by the thickness of the plate of quartz, and for the sake of convenience has been fixed at 12, the unequal dispersion making the distance between the bands in the blue about twice as great as in the red. The dark bands are numbered 1, 2, 3, 4, &c., and the centre of the white spaces $1\frac{1}{2}$, $2\frac{1}{2}$, $3\frac{1}{2}$, &c., which may be again subdivided, as into $1\frac{1}{4}$, $1\frac{3}{4}$, &c. Definite narrow absorption bands are indicated by an asterisk printed over their centre. On this notation the bands occurring in the several solutions mentioned may be described intelligibly and simply thus:—

2. Oxidized hæmoglobin . . .	$3\frac{5}{8}$—$4\frac{3}{8}$	$4\frac{3}{4}$—$5\frac{3}{4}$	8— 9—
3. Hæmoglobin with CO . . .	$3\frac{3}{4}$—$4\frac{1}{2}$	$4\frac{7}{8}$—$5\frac{7}{8}$	8— 9— and so on.

According to Mr. Gamgee,* the nitrites cause blood to assume a chocolate colour, the bands of oxidized hæmoglobin becoming very faint, and an additional absorption band in the same position as in acid hæmatin (6, Fig. 115) appearing. The nitrites do not decompose the blood-colouring matter, nor discharge the oxygen. They appear to link themselves on to it, as is probably the case with hydrocyanic acid.† Nitritized blood absorbs less oxygen, but it can convert into ozone what it does absorb. On exposure of oxyhæmoglobin to carbonic oxide gas, combination takes place, and a comparatively stable compound is formed; the solution assumes a clear cherry-red colour, and the spectrum presents two striæ, which lie rather closer together than those of oxyhæmoglobin, and are shifted a little towards the violet end of the spectrum. These do not fuse into one on the application of reducing agents, as happens with oxyhæmoglobin. If breathed, carbonic oxide proves fatal by replacing the oxygen in the blood-corpuscles and preventing the absorption of that gas.

180. There can be no doubt that both the red and the colourless corpuscles have, like other cells, a definite term of life; and that, whilst some are undergoing disintegration, others are in a state of advancing development to supply their places, so that the entire mass of both is undergoing continual change. That a new production of red corpuscles may take place with considerable rapidity, we have evidence in the rapid restoration of their normal proportion after it has been lowered by hæmorrhage, and in the speedy increase which may be effected in their amount in blood in which they have been excessively diminished by disease, this being especially promoted by the administration of iron, and by a generous diet. On the other hand, various appearances indicative of degeneration may be seen in the red corpuscles; and this especially in the blood of the Oviparous Vertebrata, which usually contains corpuscles almost destitute of colour, and having a shrunken or eroded aspect—their nuclei, however, presenting a remarkable distinctness. That, under certain circumstances, such a degenerating process takes place with great rapidity in the blood which circulates through the Spleen, may be considered as ascertained almost beyond a doubt (§ 157, III.). The duration of the individual corpuscles is unknown, the only evidence yet obtained being derived from the experiments of Bernard, who found that when the blood of birds was injected into the vessels of mammals, the elliptical corpuscles of the former, which were at first plainly visible, disappeared entirely in the course of a few weeks. The question now arises, in what manner the two classes of corpuscles are respectively developed, and whether they have any relationship to each other.

181. Coagulation of the Blood.—When the Blood has been drawn from the body, and is allowed to remain at rest, it undergoes at ordinary temperatures spontaneous coagulation, forming at first a solid mass of jelly-like consistency, of the same bulk as the liquid blood. After a time a few drops of a transparent fluid appear upon the surface of this mass; the amount of this liquid gradually increases, whilst the red solid mass—the crassamentum, or clot, as it is called—as gradually shrinks till at length the clot floats in the nearly colourless liquid or serum. The clot is composed of a network of Fibrin, presenting a more or less distinct fibrous texture; in the meshes of which the Corpuscles, both red and colourless, are involved, together with a certain amount of serous fluid, and

* "Proceedings of Roy. Soc.," No. 102, 1868.

† Preyer, Virchow's "Archiv," Band xl. 1867; and Hoppe-Seyler, "Untersuch.," 1867.

it is to the formation of this network of fibrils due to the development of fibrin in the plasma that the clot owes its origin. The serum, which is the same with the liquor sanguinis deprived of its fibrin factors, coagulates by heat, and is therefore known to contain Albumin; and if it be exposed to a high temperature sufficient to decompose the animal matter, a considerable quantity of earthy and alkaline Salts remains.—Thus, we have four principal components in the Blood: namely, *Fibrin factors*, *Albumin*, *Corpuscles*, and *Saline matter*. In the *circulating* blood, they are thus combined:—

Fibrin factors, Albumin, Salts } In solution, forming Liquor Sanguinis.
Corpuscles,—suspended in Liquor Sanguinis.

But in *coagulated* blood they are combined as follows:—

Fibrin, Corpuscles } Forming Crassamentum, or Clot, which, however, always contains more or less serum in its meshes.
Albumin, Salts } Remaining in solution, forming Serum.

The *coagulation of blood* consists in the new arrangement of its constituents, which takes place when it is drawn from the vessels, or when the body itself dies. This new arrangement essentially depends upon the conversion of a substance called plasmin into fibrin. The plasmin does not exist as such in the blood, but is formed by the interaction of two substances, fibrin and fibrino-plastin, under the influence of a ferment. These bodies will be considered in greater detail below. The clot which is thus formed is not an amorphous coagulum, but is a network of fibres more or less definitely marked out, in the meshes of which network are included the red corpuscles usually grouped together in columnar masses resembling piles of coins. The *crassamentum*, or clot, gradually acquires a firmness proportioned to the amount of fibrin which it contains and to the degree of its elaboration, and then undergoes a progressive contraction, by which the albuminous, saline, and extractive matters still in solution are more or less completely expelled from it, constituting the *Serum*. This separation will not occur, however, if the coagulation takes place in a shallow vessel, nor if the amount of fibrin happens to be small. Under such circumstances a homogeneous mass, deficient in firmness, presents itself, though the solid parts of this may pass into a state of more complete condensation after the lapse of a certain time. That the coagulation is due to the fibrin, and that the red corpuscles do not take any active share in the process, appears from several considerations.* The corpuscles, being of greater specific gravity than the plasma, or liquor sanguinis, will sink to the bottom of the vessel in which the blood is contained, provided that it is left undisturbed. Under ordinary circumstances the rapid clotting of the blood prevents this subsidence. If, however, the blood of a mammal—the horse, for example—be received into a vessel placed in a freezing mixture, and is thus kept at a

* For an admirable summary of the history of opinions in regard to the subject of blood coagulation, see the Introduction to the works of William Hewson, F.R.S., by George Gulliver, F.R.S., London, printed for the Sydenham Society, 1846. Also for experiments in regard to the coagulation o the blood, Dr. Andrew Buchanan, "Lond. Med. Gazette," vol. xviii. 1836, p. 50; and vol. i. (New Series, 1845), p. 617. The latter paper is reprinted in the "Journal of Physiology," vol. ii. p. 158, 1879. An account of Dr. Buchanan's work is also to be found in "The Natural History Review," vol. iv. 1864, pp. 157–187; and further mention of him with additional experiments by Prof. Gamgee in the "Journal of Physiology," vol. ii. 1879, pp. 145–157.

temperature below 0° C., it will not coagulate, and the corpuscles will therefore be enabled to subside. When this has taken place, the liquor sanguinis may be decanted off, and will be found to coagulate in a perfectly normal manner, the clot being colourless, and containing no red corpuscles, but a number of white ones, entangled in the mesh-work of fibrils. The same experiment may be performed by adding to the blood about one-third of its bulk of a saturated solution of certain neutral salts, such as sulphate of soda or magnesia, or carbonate of potash, which have the property of retarding coagulation. Similar results are obtained by observations on the so-called "buffy coat," which occurs in certain disorders of the blood. This coat is a layer, nearly free from colour, which is found on the surface of the clot. Its presence has been frequently regarded as a sign of the existence of inflammation, indicating an undue predominance of fibrin; but this idea is far from being correct, since, as occurs in chlorosis, it may result from an opposite condition of the blood. Its occurrence in the human subject, excepting in the female during the later stages of utero-gestation, is certainly pathological; but in some animals, as in the horse, the blood-clot is ordinarily buffy. The appearance of this buffy coat in the horse is perhaps to be explained by Cl. Bernard's observation, which shows that even during life the blood-cells gravitate to the lowest parts of the fluid. In a horse laid out on the ground in such a position that its long jugular vein was nearly horizontal, a small opening made in the upper surface allowed the escape only of the plasma, without red corpuscles, whilst from a similar small opening made at the lowest surface of the vein some very black blood issued. Both portions coagulated; the first, of course, giving a colourless clot; the second, as usual, a dark clot, with a well-marked buffy coat.* The buffy coat, then, is due to the clumping together, and consequent more rapid sinking, of the red corpuscles, and this is further shown by the fact that its appearance is hindered by artificially separating the corpuscles, whilst it is hastened or increased as their aggregation increases. Thus, as has been already mentioned, and as Mr. Gulliver has shown, solutions of neutral alkaline salts prevent the running together of the corpuscles, and retard the formation of the buffy coat. On the contrary, certain viscid matters facilitate the clumping of the corpuscles, and coincidently the quickness of the formation and the quantity of the buffy coat. Mr. Gulliver has also noticed that in fluid blood the sinking of the red corpuscles increases in a kind of arithmetical ratio, being slowest when they first begin to collect into clumps, and more rapid at the very time when these clumps are most fully formed; so that the corpuscles would in some instances take two and a half minutes at first to sink through one-eighth of an inch of liquor sanguinis; but only two and a half minutes more to sink through a further three-eighths of an inch. It is remarkable, as Gulliver† notices, that Hunter was well acquainted with the clumps of red corpuscles in inflammatory blood. The evidence is therefore satisfactory which tends to show that the red blood-corpuscles have no influence upon the cogulation of blood.

182. The influence of Fibrin upon the process of coagulation is shown by whipping the blood with a bundle of twigs, or by stirring it with a stick, when the fibrin will adhere in strings during its coagulation; and the red corpuscles will be left suspended in the serum, without the slightest tendency to coagulate. The actual cause of the separation and coagulation of the fibrin is still obscure. Dr. Buchanan‡ remarked long ago that fibrin might apparently be

* Bernard, "Leçons," 1859, p. 432.

† Lectures, "Med. Times and Gaz.," Oct. 17, 1863; Hewson's works.

‡ "Proc. Glasgow Phil. Soc.," 1845, and loc. cit.

formed, or at least that coagulation could be induced, by mixing two serous fluids like those of Hydrocele and Ascites, or of Ascites and Pleurisy, neither of which had separately any tendency to coagulate; and that coagulation was equally caused by putting into the serum portions of blood-clot, or of fibrin, either fresh or powdered, muscular fibres or other tissues. Schmidt,* in more recent observations, attempts to explain the phenomena in question by attributing them, as already mentioned, to the combination of two substances existing in the liquor sanguinis under the influence of a ferment which is rapidly formed in the blood after its removal from the body. To one of these bodies, which is contained in considerable quantity in the blood, he has given the name of Fibrino-plastin, Globulin or Crystallin, though it differs from the crystallin obtained from the lens of the eye in its non-precipitability by heat and alcohol, and has therefore been termed by Kühne Paraglobulin. It is precipitated when its alkaline solution is exactly neutralized, and is obtained from blood or other tissue which contains it, such as connective-tissue, cornea, &c., by the passage of a continuous current of carbonic acid through the greatly diluted fluid, or by saturation with one of the neutral salts which were mentioned above as retarding coagulation like common salt. The precipitate of fibrino-plastin thus obtained is at first flocculent, then granular; it is insoluble in distilled water, and is more readily isolated than Fibrinogen, the second substance which is closely allied to albumin. Fibrinogen differs from fibrino-plastin in the circumstance that its alkaline solution must be rendered acid before precipitation occurs. It is found chiefly in the plasma and in such exudations as hydrocele fluid. As ordinarily prepared, it is a viscid substance. Both Schmidt and Hoppe-Seyler have been successful in producing a coagulum differing in no respect from ordinary fibrin, by the admixture of these two substances prepared in one of the above ways. Mr. Goodman† has pointed out that ovalbumin suspended for some time in cold and pure water loses the character of albumin, and assumes the nature, appearance, and constitution of Fibrin; and he accounts for the formation of the fibrin of the blood in this way. The general explanation put forward by Schmidt in regard to the cause of the coagulation of blood is perhaps the best that can be at present offered. Plasmin, a substance discovered in blood which has been kept from clotting by artificial means, by Denis,‡ can be precipitated by

* Müller's "Archiv," 1862, p. 543. See also Mantegazza, "Annali Universali di Medicina," t. ccxvi. April, 1871. In opposition to Schmidt, see Eichwald, "Beiträge zur Chemie der gewebe-bildenden Substanzen und ihren Abkömmlinge," 1873. Eichwald regards the Fibrin as being normally dissolved in the plasma, but undergoing precipitation when exposed to the action of the carbonic acid of the air. Denis divides the Albuminous compounds of the blood into *Serin* (amounting to 52 parts per 1000 of blood), which is coagulable by heat and acids; and *Plasmin* (25 per 1000), which is precipitated by NaCl, but redissolves in from 10–20 parts of water. The plasmin is capable of breaking up spontaneously into concrete fibrin (3–4 per 1000) and soluble fibrin (22 per 1000), the proportions of which bear an inverse ratio to each other. Hence, as Sée maintains, it is never a question in disease of excess or defect of fibrin, but simply of the relative proportions of the concrete and soluble fibrin. See Küss, "Physiologie," 1873, p. 158, and Budge's "Compendium de Physiologie," 1874, p. 260. "Handbook for the Physiological Laboratory," London, 1873, p. 173; Alex. Schmidt (i.) ‡ "Ann. d. Sci. Nat.," iv. p. 25.

saturation with neutral salts, and is formed by the union of fibrinogen and fibrino-plastin. The union of these two substances is brought about by means of a ferment, that is to say, of a body which by its presence excites chemical action without itself taking part in it. The plasmin thus produced passes very readily into fibrin.*

183. That the union of fibrinogen and fibrino-plastin in the blood is brought about by means of a *ferment* is still an hypothesis, the train of reasoning, however, which has led investigators to adopt this theory is somewhat as follows:†—If the chest of a large mammal be opened immediately after death, it will be found that the fluid removed from the pericardium clots rapidly. If the opening, however, be deferred for 20 or more hours, the pericardial fluid will be found either not to coagulate at all or to coagulate very slowly and feebly. The addition of fibrino-plastin, however, effects a rapid and copious coagulation. Again, if, as Kühne‡ states, three parts of plasma be mixed with one part of a solution of magnesium sulphate, containing one part of the salt to 3·5 of water, and the whole be diluted with eight parts of water, it will be found that little or no coagulation occurs, although an excess of fibrino-plastin is present. The addition of paraglobulin to such a solution causes rapid coagulation; moreover, fibrinogen and fibrino-plastin prepared by the carbonic acid§ method, clot much less readily in a saline solution than when prepared by saturation‖ with a neutral salt. A watery extract of blood is readily obtained by pouring blood into a large excess of alcohol; it must not be allowed to flow into the alcohol directly from the artery, otherwise, according to Hermann, the desired result is not obtained. It is allowed to remain for some weeks below the alcohol, to precipitate all the proteid matters. The spirit is then decanted and evaporated off, and the residue, after being dried at a temperature below 40° C., is extracted with water. An aqueous solution of the alcoholic precipitate is thus obtained, which contains substances dissolved or suspended in it which, though soluble in water, are insoluble in alcohol. This extract gives only very slight proteid reactions; if, however, a small quantity of it be added to the plasma mentioned in the second experiment, or to some of the pericardial fluid, coagulation rapidly occurs. In the aqueous solution there is present some principle which is capable of causing coagulation in fluids containing both fibrinogen and paraglobulin (fibrino-plastin), though it does not do so in those cases where there is reason to suppose that only one of these bodies is present. It is this principle which is known as the ferment, and it belongs to that class of ferments known as unorganized, to which allusion has already been made (§ 68). This ferment effects coagulation only in relation to the rapidity with which that phenomenon sets in, for if a larger quantity of the aqueous extract be added it will be found that coagulation sets in more quickly, though there is no increase in the amount of the clot; consequently the ferment is essential to the union, or at least interaction of the two fibrin factors, though it does not contribute to the formation of the clot. The question then arises, where is this ferment in the normal condition of the blood? Undoubtedly it is not usually present. Hermann observes that it

* Prof. Schmidt is doubtful as to whether fibrin is formed by the actual union of fibrinogen and fibrino-plastin; it is therefore better to leave this point open, and to state that fibrin originates by the interaction of fibrinogen and fibrino-plastin, under the influence of a ferment.

is developed only at the death of the blood, hence his caution in preparing the alcoholic extract, against allowing the blood to flow directly from the vessel into the alcohol.

184. As Mantegazza* has observed, the presence of white blood-corpuscles is necessary for coagulation; since it is well known that a clot is formed wherever the endothelium of a vein is irritated so as to undergo germination. The observations of Mantegazza are abundantly confirmed by facts: thus, to take a few cases. It is found that if the red blood-corpuscles be removed as completely as possible by subsidence and decantation under the circumstances already described (§ 181), and be added to a quantity of serum which is equivalent to the amount of blood from which they were removed, the serum will clot. This coagulation, however, is not due to any influence exercised by the red blood-corpuscles, as has already been shown. Again, Müller placed the blood of a frog diluted with water, or still better 0·75 per cent. sodium chloride solution, on a paper filter. The plasma passed through completely unmixed with red corpuscles, but it presented a distinct coagulum, although from the diluted state of the fluid this did not possess much consistency. In this experiment it is found that the white corpuscles, from their extreme lability pass through the filter at the ordinary temperature,† and that it is only when the whole operation is conducted at a temperature of 0° C. that the white corpuscles can be filtered off. When this precaution has been taken and the white corpuscles have been separated, the plasma refuses to clot, though it does so on addition of the white corpuscles. The lymph from blisters, which contains no red corpuscles, but numerous white ones, coagulates normally. Schmidt‡ also gives the following experiment as being a good example of the influence of the white corpuscles on the coagulation of the blood:—The blood is allowed to flow into a deep vessel which is surrounded with ice to retard coagulation, the red blood-corpuscles subside, and a clear stratum is left which contains many white corpuscles. The clear stratum is carefully decanted on to an ordinary filter-paper, which is also kept at a freezing temperature. A transparent filtrate free from white corpuscles is thus obtained. This filtrate has lost its power of coagulation, since the liquid may be kept for several hours in a room at the ordinary temperature. The colourless corpuscles may be freed from any adherent plasma by washing with ice-cold water. The white corpuscles are then broken up by pouring on to them a little water rendered slightly alkaline with sodium carbonate, when a solution passes through which causes immediate coagulation. Brown-Séquard§ has made the curious observation that on injecting defibrinated blood into the separated limbs of animals, fibrin is formed, especially if the muscles are tetanized: similar results have also been obtained by Bernard.‖ It is remarkable, moreover, that splenic venous blood, which contains an excess of white corpuscles, when defibrinated will on exposure to the air form a second coagulum. Professor Schmidt, of Dorpat, whose investi-

* Mantegazza (Moleschott's "Untersuch. zur Naturlehre" Band xi. p. 523; "Centralblatt," 1877, p. 23) has recently advanced a theory of coagulation, in which he regards it as an expression of vitality, instead of, as Schmidt regards it, a phenomenon associated with the death of the blood. Mantegazza looks upon it as a phenomenon of reaction of the white corpuscles to some stimulus usually of a foreign body, or some roughness of the internal coats of the vessels; at any rate, if any such roughness exist it is quickly covered with white corpuscles and fibrin, whilst no fluid coagulates unless it contains white corpuscles. Beltrami thought that fibrin was the detritus of muscular substance, and Lussana adopted this view because he found more fibrin in the blood of tetanized animals, but Mantegazza, on the other hand, observed a diminution rather than an increase.

‖ "Leçons," 1859, vol. i. p. 460.

gations have been mentioned above,* has published the results of his many years' laborious researches upon this subject, and he, too, has come to the conclusion that the colourless corpuscles of the blood exert a very material influence upon the coagulation of that fluid. He has noticed that previous to the occurrence of coagulation in the blood a certain number of the leucocytes undergo disintegration. From this breaking up that ferment probably proceeds which causes the fibrino-plastin to interact with the fibrinogen in such a way as to produce the substance known as Fibrin; or, in other words, the blood ferment is contained within the white blood-corpuscles. Professor Schmidt† bases his theory essentially upon the fact that if freshly-drawn blood be examined without delay, the white corpuscles may be seen to break up into granules; these granules for a time cohere in the liquid, but they eventually dissolve and disappear; whilst from the heaps of granules thus formed, and more particularly from those which belong to the transitional forms of white corpuscles containing coloured particles, the first-formed filaments of fibrin can be seen to originate.

185. The theory of a ferment present in the white blood-corpuscles, which is set free on their disintegration, explains a great number of facts in regard to the coagulation of blood. Still it must be remembered that it is as yet but a theory, which has to be proved by facts. Upon this assumption the caution given by Hermann is to be explained, for he recommends, as before stated (§ 183), that blood should be allowed to flow into an intermediate vessel, and not directly into strong alcohol, for by this means the disintegration of the white corpuscles is to a considerable extent insured; whereas, if the blood passed directly from the vessels into an excess of alcohol, the white corpuscles might be so hardened that little or no ferment would be liberated. An explanation is likewise afforded of the fact that the fibrillation is the more perfect the more slowly it takes place; that the coagulation of such blood as is met with in conditions of acute inflammation, which produces a clot of remarkable firmness, is much longer in taking place than the coagulation of ordinary blood; whereas the blood of cachectic subjects, which clots very rapidly, is feeble and imperfect. The plastic effusions poured out from the blood in these two opposite conditions partake of the character of the blood itself; those of the inflammatory blood of a previously healthy subject being converted into fibrous membranes of considerable firmness, which are subsequently penetrated by blood-vessels, and become regularly organized tissues. Those, on the other hand, which proceed from the blood of cachectic subjects frequently undergo a degree of organization with great rapidity, but do not attain the same perfection, and speedily degenerate.‡ Further, that the contact of a dead substance promotes coagulation,§ even in the living and actively moving blood, is shown by the experiment first performed by Mr. Simon, of carrying a single thread transversely (by means of a very fine needle) through an adjacent artery and vein in a dog. The thread is allowed to remain in position for a period of from twelve to twenty-four hours, when a coagulum is formed which more or less completely obstructs the vessel; whilst the thread itself is found on examination to be covered with colourless corpuscles. In such experiments there is a marked difference between the coagula formed in

§ Lister, 'Croomian Lect.,' "Lancet," 1863, vol. ii. p. 179.

the artery and those formed in the vein, which may be attributed to the difference in the rate of the blood-current. The thread which traversed the artery usually presents a "vegetation" on its surface, sometimes as large as a grain of wheat, always of a pyramidal shape, with its base attached to the thread, and its apex down stream. The venous coagulum is a voluminous black clot, chiefly collected on that side of the thread which is most remote from the heart.* The explanation of this is to be found in the fact that injury to the endothelium lining of the vessels causes a germination or proliferation of white corpuscles, some of which becoming broken up liberate the ferment. That this is the case is shown by the fact that blood which has been allowed to coagulate, and has been strained from the clot, acts as a rapid poison when re-injected into the arteries of the animal from which it was taken; the cause of death in such a case being embolism in the capillaries.† M. Dupuy, and afterwards M. de Blainville, in like manner found that the injection of cerebral substance into the veins of an animal occasioned its death almost as instantaneously as if prussic acid had been administered; the circulation, as in the case after the injection of cruorin in the previous experiment, being rapidly brought to a stand by the formation of voluminous clots in the heart and large vessels.‡ There is no reason to suppose that cerebral substance possesses a more special influence than would be exerted by any other tissue which could be as easily mixed up with the circulating current, for in both cases the presence of the injected fluids suffices to determine coagulation in blood in which it would not otherwise have occurred. The same effect is produced with still more potency when the substance injected is rather undergoing degradation than actually dead, as is well observed in the case of pus, noticed originally by Hunter and afterwards by Mr. H. Lee. Healthy blood received into a cup containing some offensive pus coagulated in two minutes; whilst another sample of the same blood received into a clean vessel of similar size and shape required fifteen minutes for its complete coagulation. Mr. Lee found that when pus was injected into the jugular vein of a living ass, coagulation took place so instantaneously as to produce an immediate obstruction to the current of blood, so that the vessel at once acquired a cord-like character; and in this mode the pus was usually prevented from finding its way into the general current of the circulation. Whilst it thus remains circumscribed by a coagulum of blood, the pus so introduced seems to produce no other constitutional disturbance than is attributable to the local injury; but if the circumscription should be incomplete, and the pus should be carried into the general circulation, it becomes a source of extensive mischief, determining the formation of abscesses in various parts, and producing a most depressing influence on the system at large.§ These facts are explicable, as in the case of the injection of cruorin or filtered blood-clot, by assuming that the white corpuscles break up under certain influences, and set free a ferment which in presence of the two fibrin factors, fibrinogen and fibrino-plastin, causes them to interact in such a way as to form plasmin, which in turn is converted into fibrin. In like manner may be explained the observation that when the coagulum of blood from which the fibrin has been removed by whipping, is frozen and allowed to thaw again, a further coagulum is obtained, because some of the white corpuscles which had escaped disintegration in the first instance are then broken up, and a fresh supply of ferment is liberated. As also Mr.

‡ "Gaz. Med.," 1834, p. 521.

§ "On the Origin of Inflammation of the Veins and Purulent Deposits."

Thackrah's* experiments, that coagulation occurs more rapidly in rough vessels than in smooth, and in metallic than in those of glass and earthenware, since there is less disintegration of white corpuscles in the former than in the latter. Mr. Thackrah found that the quantity of serum separated from blood-clotting in metallic vessels is much less than that obtained from a similar coagulum in an earthenware vessel; thus, in one instance the proportion was as 10 to 24·5 when the blood coagulated in a glass vessel, whilst a portion of the same blood coagulating in a pewter vessel gave only 10 of serum to 175 of clot. The specific gravity of blood is no measure of its coagulating power; for a high specific gravity may be due to an excess in the amount of corpuscles which form the heaviest part of the blood, and may be accompanied by a diminution of the fibrin factors, which are the coagulating elements.

The ferment theory which is here adopted does not, however, explain all the phenomena of the blood coagulation, for it is found that blood returning from the kidneys and liver has little or no tendency to coagulate, in spite of the fact that like the blood of the splenic vein an excess of white corpuscles is found in the renal and hepatic veins. In the same way, no explanation is afforded of the fact that the hearts of cold-blooded animals may be kept full of blood for several days after removal from the body without the occurrence of coagulation; nor is Lister's† experiment explained, in which the jugular vein is ligatured at the bottom and a piece of it is excised, this portion being filled with blood, no coagulation takes place for a long period, and blood may be poured from one preparation‡ to a second without coagulation occurring. So also the observation of Schroeder van der Kolk§ that if the substance of the brain and spinal marrow be destroyed coagulation of the blood takes place whilst it is still moving in the vessels, clots being found in them even within a few minutes of the operation, is still left without explanation.

186. Instances occasionally present themselves, in which the blood does not coagulate after death, or coagulates very imperfectly. It was affirmed by Hunter‖ that no coagulation occurs in the blood of animals hunted to death, or of those killed by lightning, by electric shocks, or by blows upon the epigastrium; and this statement has been generally received upon his authority. It is far, however, from being constantly true; for Mr. Gulliver has made observations and collected numerous cases in which coagulation was found to have taken place in the blood of animals killed in each of these modes; in some of them, however, the coagulation was very imperfect.¶ It is not improbable that some of the instances of apparent *absence* of coagulation were really cases of *retarded* coagulation; and Dr. Polli goes so far as to maintain that the complete absence of coagulating power is a phenomenon which has no real existence. He states that he has never met with an instance in which the blood, when left to itself, and duly protected from external destructive influences, did not coagulate before becoming putrid; and that he has more than once found blood to coagulate, which had been taken in a fluid state from the vessels thirty-six or forty-eight hours after death.** Still there seems no reasonable doubt that non-coagulation *may* occur, when the blood has been previously subjected to conditions which affect its vitality. Such

** "Annali Universali," 1845; and Ranking's "Abstract," vol. ii. p. 337.

appears to be the case, for example, when death occurs from Asphyxia, as by hanging, drowning, or breathing of irrespirable gases;* and the same has been observed in cases of poisoning by hydrocyanic acid, in which asphyxia was probably the immediate cause of death. In like manner certain animal poisons when introduced into the current of the circulation—as by the bite of venomous serpents—appear like a high temperature to entirely prevent the coagulation of the blood. In certain diseased states, again, the coagulating power seems to be completely deficient.

187. The rapidity of Coagulation, and the degree in which the clot solidifies, vary considerably; in general, they are in the inverse proportion to each other. Thus, if a large quantity of blood be withdrawn from the vessels of an animal at the same time, or within short intervals, the portions that last flow coagulate much more rapidly, as originally proved by Hewson, but much less firmly, than those first obtained. In blood drawn during Inflammatory states, again, the coagulation is usually slow, but the clot is preternaturally firm; especially at its upper part, where the Buffy coat (§ 181) or colourless stratum of fibrin gradually contracts, and produces the "cup," which may be generally considered to indicate a high degree of inflammation. The physical changes to which the blood is subjected when drawn from the vessels are, that it is brought to rest, that its temperature is reduced, and that it is exposed to the action of the air. It may easily be shown, however, that its coagulation cannot be attributed to either of these conditions. For, in the first place, if the blood be continually agitated in a bottle, though its coagulation is delayed, it will at last take place in shreds or insulated portions; yet that rest is not the cause of its coagulation (as some have supposed) is proved by the fact that, if a portion of blood be retained in the excised heart of a frog or turtle† by ligature of the vessels, or be included between two ligatures in a living vessel, it will, as mentioned above, remain fluid for a considerable time;‡ as it also will when effused into the midst of living tissues, or kept in a state of stagnation in parts affected with inflammation. Thus, Mr. Gulliver, besides other instances, mentions a remarkable case witnessed by himself, in which a collection of blood which had been effused in consequence of a bruise on the loins, was found uncoagulated when let out twenty-eight days afterwards; it measured five ounces, was as liquid as blood just drawn from a vein, and showed the normal characters when examined microscopically; and it coagulated in a cup in less than thirty minutes.§ And Sir James Paget mentions that he has known the blood remain fluid in the vessels of an inflamed part, though in a state of complete stagnation, for as long as three days.‖—Again, so far from coagulation being promoted by cold, it can be shown to be accelerated by moderate warmth, the natural heat of the body from which the blood is taken appearing to be most favourable to it; but the coagulating power appears to be destroyed by a temperature of about 150° F., blood heated to that point remaining permanently fluid.¶ On the other hand, the coagulation is retarded by cold; but the

* See Dr. J. Davy's "Physiological and Anatomical Researches," vol. ii. p. 191.

† "B. and F. Med.-Chir. Rev.," xix. p. 183, 1857.

‡ The testimony of all experimenters is in accordance on this point, although they differ as to the length of time that elapses before coagulation commences. Mr. Gulliver states that out of many trials made by him, the coagulation commenced within two hours in only a few instances; more commonly three, four, or five hours elapsed before any clot was formed; and in one instance the coagulation was incomplete at the end of twenty-four hours. In all these experiments, the blood coagulated in the course of a few minutes when withdrawn from the living vessels.—See Mr. Gulliver's edition of "Hewson's Works," p. 23.

§ Op. cit., p. 17.

¶ Gulliver, op. cit., pp. 4, 5.

coagulating power is not destroyed even by extreme cold. Lastly, although coagulation is accelerated by exposure to air, it is not prevented by complete exclusion from it, as is proved by its taking place in a vacuum, or in a shut sac within the dead body; complete exclusion from the air, however, does retard the change, as may be easily shown by causing blood to flow into a vessel containing oil, which will form an impervious coating on its surface, and will occasion the coagulation to take place so slowly, that the red particles have time to subside, and the upper stratum of the clot to be colourless.*—The effect of the addition of strong solutions of neutral salts to fresh blood is usually to retard, and sometimes even to prevent, its coagulation; it is retarded also by pepsin,† and the same effect is produced by many vegetable substances, particularly those of the narcotic and sedative class, such as opium, belladonna, aconite, hyoscyamus, digitalis, and tea or coffee in strong infusion.‡ The action of most of these substances, however, which preserve the fluidity of the blood, only continues during such time as their solutions retain a certain strength; for if they be diluted coagulation will then take place, although in most cases less perfectly than it would have done at first. There appears to be no limit to the time during which the coagulation may be thus postponed; thus, Mr. Gulliver mentions that he has kept hare's blood fluid with nitre for fifty-seven weeks, and that it still readily coagulated when diluted with water.§ It is not so difficult therefore, as it might otherwise seem, to give credit to the statement of Dr. Polli,‖ that in a case witnessed by himself, complete coagulation of the blood did not take place until fifteen days after it had been withdrawn from the body, and that fifteen days more elapsed before putrefaction commenced in it. The upper four-fifths of the clot were colourless, the red corpuscles occupying the lowest fifth. It is additionally interesting to notice that the patient (who was suffering under acute pneumonia), being bled frequently during the succeeding week, the blood gradually lost its indisposition to coagulate, for as more blood was drawn, more white corpuscles would be found in it, and consequently more ferment would be liberated. Neither heat, ammonia, nor carbonic acid appear to be evolved, as was formerly supposed, during coagulation.

188. *Development of the blood corpuscles.*—The *first* Red corpuscles unquestionably have their origin, like the original cells of the solid tissues, in the primordial cells of the germinal structure; and it is in the 'mesoblast' or so-called 'vascular layer' of the 'blastodermic vesicle' (CHAP. XVIII. sect. 4), and the mass of cells which constitute the rudiment of the heart, that this metamorphosis seems first to take place. The situation of the heart, and the course of the principal trunks of the 'vascular area,' are early marked-out, by the peculiar disposition of the aggregations of cells from which these organs are to be developed; and whilst the *outer* portions of these aggregations are transformed into the *walls* of the respective cavities, the *inner* portions seem partly to deliquesce, and partly to remain as isolated cells floating in the liquid thus produced. These isolated cells are the first blood-corpuscles; and the following account of them in the Oviparous Vertebrata or Pyrenæmata is

given by Foster and Balfour,* and differs but slightly from that by Klein:†—In the pellucid area, where the formation of blood-vessels may be most easily observed, a number of mesoblastic cells are seen to send out processes which unite and form a protoplasmic network, with nuclei at the points from which the processes started. The nuclei, which as a rule are much elongated and contain large oval nucleoli, increase very rapidly by division, and form groups at the nodal points. The majority of these acquire a red colour, and become converted into blood-corpuscles, but a few, generally on the outside of the group, remained unaltered. The protoplasm *in* which the central reddened nuclei are imbedded becomes liquefied, whilst that on the *outside* of each group as well that of the uniting processes remains granular and forms an investment for the unaltered nuclei which are imbedded in it. Each nodal point is thus transformed into a more or less rounded mass of blood-corpuscles floating in plasma, but enveloped by a layer of nucleated protoplasm, the several groups being united by strands of nucleated protoplasm. By the growth of the strands and the transformation of nuclei in their interior a series of communicating vessels is formed containing corpuscles which when removed from the vessels exhibit energetic amœboid movements, and probably increase by division.‡

189. That after the Chyle and Lymph have begun to flow into the circulating current, the *continued* generation of Red corpuscles is due to the progressive metamorphosis of those fluids, is an opinion which has come of late to be very generally received amongst Physiologists; it may be found, however, to require some modification. It rests upon the facts of three different orders:—1st, the presence, in the blood of oviparous Vertebrata, of corpuscles exhibiting what appear to be intermediate gradations of development between Lymph-corpuscles and the nucleated Red corpuscles, and this especially in blood in which an unusually rapid development of red corpuscles is taking place, to make up for previous loss; 2nd, frequent ruddiness in the hue of the fluid of the Thoracic duct, which seems to depend upon the incipient development of Hæmoglobin in some of its floating corpuscles; and, 3rd, the progressive transition from one form to the other, which may be observed in the ascending scale of animal existence. As to the precise mode, however, in which the non-nucleated Red corpuscles of Mammalian blood are produced, much difference of opinion still exists. The most probable view is that the ordinary

* "Elements of Embryology," 1874, p. 69.

‡ A different account has lately been given by Dr. H. D. Schmidt, *Monthly Microscopical Journal*, 1874, p. 45, from observations made on a very early human embryo. In this case the young coloured corpuscles appeared to be developed in the interior of mother-cells, at the expense of which they grew, and from which they ultimately became detached, leaving a dimple at the point of separation. One, two, or three young corpuscles were sometimes seen in a parent corpuscle, and the young ones themselves sometimes had a third generation in their interior prior to their own escape. This method of increase forms, as Dr. Schmidt observes, the transition from endogenous development to generation. The parent cells themselves appeared to be derived from the interior primary glandular follicles, formed of hexagonal cells in the walls of the umbilical vesicle, and he is of opinion that the so-called nuclei of the first set of blood-cells are in reality the embryonic red blood-corpuscles which, when first formed, exactly resemble the corpuscles of the adult, except that the central depression is less distinct. See also Schäfer, "Proceed. Roy. Soc.," xxii. No. 151, p. 243, who shows that blood-corpuscles arise in the interior of the vacuolated and nucleated cells of connective tissue; the hæmoglobin being deposited in the form of minute globules, which increase in size and form the corpuscles, whilst the cells elongating, branching, and uniting with others form the vessels.

lymph-corpuscle may either develop into a white corpuscle, or into a red corpuscle.* M. Hayem† gives the following account of certain cells, to which he has given the name of *Hæmatoblasts*, which he has found in the blood of the oviparous vertebrata, that is to say, in the Ichthyopsida, and Sauropsida :—These are destitute of colouring matter, yet differ essentially from the colourless corpuscles of the blood, and develop into perfect red corpuscles. The hæmatoblasts are at first very pale and delicate, of an angular and elongated form, with a solitary nucleus which is clearer than the body of the corpuscle, and which resembles the nucleus of the red blood-corpuscle, except that it is a little smaller and is less elongated. At this stage the hæmatoblasts differ from the white corpuscles, by the greater transparency and feebler refracting power of their protoplasm, and by their viscosity which causes them to adhere to one another, and so form masses of considerable size. As the development of the corpuscles proceeds the viscosity is lost, and the appearance of small discs is gradually assumed, whilst at the same time the hæmatoblasts become more darkly coloured, and the nucleus occasions a prominence on each side of the disc; at a still later period the protoplasm is reduced to a narrow ring round the nucleus, and the corpuscle assumes a shape resembling that of the developed red corpuscle. The colouring matter usually appears before the development of the cell is completed. All reagents act upon the hæmatoblasts just as they do upon the red blood-corpuscles, and produce none of the effects manifested by the leucocytes.‡ In no case are these hæmatoblasts less numerous than the white corpuscles, but, on the contrary, they may be twice as numerous. Mr. Wharton Jones still holds the view originally maintained by Hewson, that the red corpuscles of Mammalia proceed from the nuclei of the pale corpuscles; and it is almost certain that amongst the apyrenæmata the entire white corpuscle does not become the red corpuscle, though various observers have endeavoured to show that the pale nucleated cells of the pyrenæmata do pass into the coloured nucleated red corpuscle of this section of vertebrata. In that case the difference in the mode of development would appear as remarkable as the difference in the perfect structure, already described, of the red corpuscles of these two main divisions of Vertebrata. Under any circumstances the Chyle and Lymph seem to be continually supplying, not merely the *pabulum* for organization, derived from the food, whereby the components of the liquid part of the blood are replenished as fast as they are withdrawn; but also the rudimentary *corpuscles* which are to be progressively metamorphosed into the particles that float in its current. In one or two instances, under exceptional circumstances, the red blood-corpuscles have been seen to be undergoing fission.

190. *Composition of the Blood.*—The morphological or formed elements of the Blood having been thus separately described, we have now to inquire into the chemical characters of the various components which are associated in the liquid as a whole, and the proportions in which they severally present themselves. These are subject, even within the limits of health, to considerable variations; some of which seem to depend upon the constitution of the individual, his diet, mode of life, &c.; whilst others are probably referable to the period at which the last meal was taken, and the amount of bodily exertion made within a short time previous to the analysis. Taking the blood of the horse, Hoppe-Seyler found the following proportions:—

* See Dr. Bennett, "Lancet," vol. i. 1863, p. 378.
† Académie des Sciences. ‡ "Lancet," Dec. 29, 1877, p. 966.

In 100 parts of Blood.

Plasma, 67·38		Blood corpuscles, 32·62	
In 100 parts of Plasma		In 100 parts of Blood-corpuscles.	
Water	90·84	Water	56·50
Solids	9·16	Solids	43·50

Relative proportion of the Solids.		100 parts of dry Blood-corpuscles (Dog).	
Fibrin	1·01	Albumins	12·55
Serum albumin	7·76	Hæmoglobin	86·50
Fats	0·12	Lecithin	0·59
Extractives	0·40	Cholesterin	0·36
Soluble salts	0·64		
Insoluble salts	0·17		

191. We have now to notice those less prominent components of the Blood which have not been hitherto described in detail. Under the general head of *Fatty Matters* are included several different kinds of fat; of which the most important are the saponifiable fats, stearin, palmitin, and olein; the phosphorized fats or glycerin-phosphoric acids, which appear to originate from the decomposition of Lecithin (§ 56) in the blood, and cholesterin. The proportion of the saponifiable fats is always considerably increased after food, the increase proceeding from the entrance of the oleaginous chyle (§ 139). The kind of food will, however, of course materially affect the quantity of fat contained in the blood. Nasse found 2·6 parts of fat in 1000 of the blood of a dog that had been kept fasting for 4 days. After bread diet it rose to 3·1 parts, after meat to 3·8, and after suet and starch to 4·1 parts in 1000.—The following Table represents the mean, maximum, and minimum amounts of fatty substances in the healthy blood of Man (the proportion in that of the female being almost precisely similar), according to the analyses of MM. Becquerel and Rodier:—

	Mean.	Max.	Min.
Saponified fat	1·004	2·000	·700
Phosphorized fat	·488	1·000	·270
Cholesterin	·088	·175	·030
Serolin	·020	·080	inappreciable.

The source of the peculiar *odour* of the blood is probably a volatile fatty acid, too minute in its amount to admit of being separately estimated. This odour may be made much more apparent by treating the blood with sulphuric acid, even after it has been long dried; and in all those animals which are readily distinguishable by their odorous emanations, it may thus be made so perceptible as to admit of their blood being distinguished (at least by an individual possessed of a delicate sense of smell) through its scent alone. Of this test, use has been made with great advantage in juridical investigations.*

192. Under the vague term *Extractive*, have been included many different substances which normally present themselves in only very small quantity, and which are consequently difficult of detection, but which are extremely important in a physiological point of view, as the chief "factors" (to use the appropriate designation of Prof. Lehmann) in the metamorphosis of animal tissue, both *progressive* and *retrograde*. Amongst the latter, Urea, Kreatin, and Kreatinin; Uric, Hippuric, and Lactic Acids, Leucin, Tyrosin, and

* See M. Barruel's researches on this subject in "Ann. d'Hygiène," &c., tomes i., ii., and x.

Hypoxanthin (or Sarkin), may be particularly mentioned. Besides the foregoing, the extractive of blood generally seems to contain Sugar, or an amyloid substance, which is found most abundantly in the blood of the hepatic vein, vena cava, and pulmonary artery. As might be expected, the proportion of sugar in the blood is greatly affected by the diet of the animal. Plosz and Tiegel* have described a saccharifying ferment in the blood, and Hudson Ford† maintains that alcohol derived from the decomposition of sugar is normally present.—The very small amount in which the Blood-constituents of this class normally present themselves is readily accounted-for by the fact that they are only *en route* between the tissues and the excretory organs which are destined for their elimination; so that as long as the disintegrating processes taking place in the former are balanced (as they should be) by the activity of the latter, these substances are withdrawn from the blood-current as fast as they are introduced into it, and no sensible accumulation will occur. It can scarcely be doubted that the more attentive study of this part of the blood, prosecuted upon large quantities at once, will be attended with the discovery of many facts that would throw great light upon the Chemistry of the histogenetic operations, and of the retrograde metamorphoses of the effete materials of the tissues.

193. No list of the *Inorganic Constituents* of the Blood which has yet been given expresses the precise mode in which they are grouped together; for both the blood-corpuscles and the plasma contain phosphoric acid in combination with lecithin, and this acid, when the blood is incinerated, expels carbonic acid from its combinations, and if in excess of the carbonates also decomposes the chlorides, setting the chlorine free. So, again, in the incineration of albumins with sodium carbonate and free access of air, sulphates are formed by the oxidation of the sulphur in albumin. Schmidt found in 1000 parts by weight of blood of Man—

Potassium	1·739	Phosphoric acid	0·766
Sodium	1·902	Calcium phosphate	0·193
Chlorine	2·620	Magnesium phosphate	0·137
Sulphuric acid (SO_3)	0·094	Oxygen (estimated)	0·427

or about 8 parts in 1000. He has also attempted to give the distribution of the bases and salts in the corpuscles and plasma respectively, as is shown in the following Table—

In 1000 parts of Blood are contained

Plasma	487
Blood-corpuscles	513

1000 parts of Blood-corpuscles contain				1000 parts of Plasma contain			
Water, 681·63				Water, 901·51

‡ For fuller details the reader is referred to Hoppe-Seyler, "Physiol. Chemie," 1879, p. 451; and C. Schmidt, "Zur Characteristik d. Epidem. Cholera," Leipzig, 1850.

In Carnivorous animals the Phosphates, in Herbivorous the Carbonates, are in excess, which is obviously related to the difference of their diet. The normal presence of various metals in the blood has been alternately admitted and denied. Iron is unquestionably always present, and amounts to 0·42 per cent. of the hæmoglobin present.* Millon† found in 100 parts of the insoluble residue of the ash of blood 1 to 3 parts of silicon, 1 to 5 parts of lead, 0·5 to 2·5 parts of copper, and from 10 to 24 parts of manganese.‡ A trace of lithium has been discovered by means of the spectroscope (Folwarzny), and Küss admits a small proportion of arsenic.

194. We have now to inquire into the principal modifications which the relative proportions of these constituents undergo in the state of health, under the influence of varying conditions of the system; and notwithstanding the want of *absolute* correctness in the analyses of which we are at present in possession, those that are made by similar methods give results sufficiently trustworthy to enable them to be compared together, and thus to give a tolerably correct indication of the circumstances which determine the *increase* or *diminution* in the principal components of the blood.—The first of these modifying conditions which requires special notice is *Age*. During the latter part of fœtal life, the blood is remarkably rich in red blood-corpuscles and in iron, but contains less albumin, fat, and fibrin, than that of adults.§ The larger quantity of solid constituents in the blood of the fœtus appears to continue for a short time after birth; but it rapidly diminishes, and the whole amount of solid matter in the blood seems to fall to its lowest point during the period of childhood. Towards the epoch of puberty, the amount of solid matter increases again, the chief augmentation being in the corpuscles; and it remains at a high standard during the most vigorous period of adult life, after which it begins to decline. In old age it contains more water, fibrin factors, salts, and cholesterin, the number of corpuscles being less. This is made apparent in the following Table, deduced from the analyses of Denis, which are confirmed by those of Lecanu and Simon:‖—

						Solid Constituents.
In	5	individuals	between	5 months	and 10 years	170
	13	„	„	10 years	and 20 „	200
	11	„	„	20 „	30 „	240
	12	„	„	30 „	40 „	240
	6	„	„	40 „	50 „	240
	8	„	„	50 „	60 „	220
	9	„	„	60 „	70 „	210

The amount of oxygen in the blood also decreases towards the end of life.

195. An appreciable difference exists between the blood of the two *Sexes;* that of the male being from 12 to 20 per cent. richer in solid contents than that of the female, the excess being particularly observable in the proportion of the corpuscles. The blood of the woman is of less sp. gr. and of brighter colour. The serum contains less salts, though the total quantity of salts in the blood is

* See Fudakowski, "Centralblatt f. d. Medicin. Wiss.," 1866, p. 705.

† "Annal. de Chim. et de Phys." sér. iii. t. xxiii. p. 372.

‡ Melsens ("Annal. de Ch. et de Ph.," xxiii. p. 358) denies the presence of copper and lead and Béchamp ("Journ. de la Phys.," 1860, vol. iii. p. 211) appears to think the occurrence of all or any of these metals to be merely accidental.

§ Panum (Virchow's "Archiv," 1864, Band xxix. p. 481) found the blood of the new-born dog contained from 19·26 to 22·8 of solids, whilst that of the mother contained only 13·8 per cent. Leichtenstern ("Untersuch. üb. d. Hæmoglobingehalt des Blutes," Leipzig, 1878, p. 32) found the proportion of Hæmoglobin in the new-born dog as compared with the mother to be as 96 : 53.

‖ "Animal Chemistry," vol. i. pp. 237–239.

larger.* The corpuscles are fewer, but the albumin, fats, and extractives are present in larger proportions.† There is no doubt, also, that the proportions of the constituents vary considerably with individual *temperament* and *constitution;* the proportion of the whole solid constituents, and especially of the corpuscles, being considerably greater in individuals of the plethoric or 'sanguineous' temperament than in persons of the 'lymphatic' temperament; and it appears from the analyses of Lecanu,‡ that the sexual difference in the blood almost disappears when the blood of males and of females of the latter temperament is compared. There is no material change in the composition of the blood in the early months of pregnancy, but in the later stages the albumin and red corpuscles diminish, and there is an increase of fat, fibrin, water, and salts.§

196. A considerable influence is exercised on the entire amount, and on the relative proportions, of the constituents of the blood, by the previous ingestion of *Food or Drink*, and by the *Diet* habitually employed. When a full meal containing oily matter is taken after a long fast, and a small quantity of blood is drawn previously to the meal and at intervals subsequently, the serum, though quite limpid in the blood first drawn, shows an incipient turbidity about half an hour afterwards; this turbidity increases for about six hours subsequently, after which it usually begins to disappear. The period at which the discoloration is the greatest, however, and the length of time during which it continues, vary according to the kind and quality of the food, and the state of the digestive functions. When such milky serum is examined with the microscope, the opacity is found to be partly due to an increase in the amount of white corpuscles, and partly to the presence of an immense number of exceedingly minute granules, identical with those which form the 'molecular base' of the chyle (§ 155). They seem to be composed of two chemically distinct substances; for when the milky serum is agitated with ether, a part is dissolved, whilst another portion remains suspended; and this latter is soluble in caustic potash. The former, therefore, appears to be identical with the 'molecular base' of the chyle, and to be of an oily or fatty nature; whilst the latter belongs to the protein-compounds, and probably constitutes the haptogen membrane of Ascherson, by which all fatty particles floating in an albuminous fluid, immediately become invested. The Crassamentum of such blood often exhibits a pellucid fibrinous crust, sometimes interspersed with white dots; and this seems to consist of an imperfectly assimilated protein-compound, analogous to that found in the serum. The quantity of this varies according to the amount of the protein-compounds present in the food. The quantity of oxygen contained in arterial blood is diminished during digestion.—The increase of *saccharine* matter in the blood (in which it forms part of the 'extractive'), after the ingestion of a large quantity of saccharine or farinaceous aliment, has been noticed by many experimenters. Its proportion differs much in different parts of the body. It might be fairly presumed that a temporary augmentation must take place in the *aqueous* constituent of the blood, whenever any considerable quantity of liquid is ingested; and yet this augmentation is much less considerable, under ordinary circumstances, than we should at first be

* Beaunis's "Physiology," p. 105.

† In advanced pregnancy in the *dog*, Nasse ("Archiv f. Gynæcol.," Band x. 1877, p. 315) found that there was diminution in the sp. gr. of the blood with increase in the proportion of water, fat, fibrin, and salts. The blood only returned to its normal condition after lactation had ceased.

‡ "Etudes Chimiques sur le Sang humain," p. 66; and Simon's "Animal Chemistry," vol. i. p. 236.

§ See Nasse, "Archiv f. Gynæcol.," Band x. 1877, p. 315.

inclined to suppose. For there exist various provisions in the system (the peculiar Malpighian apparatus of the kidneys being the chief) for rapidly freeing the blood from any superfluity of water; and thus any excess of fluid absorbed is speedily drawn off again. But further, it is certain that when the vessels are already filled, absorption does not take place with nearly the same readiness as after long abstinence from liquids; the rate of absorption being in great degree governed by that at which the liquid is disposed of. The influence of the *Regimen* upon the composition of the blood, however, appears to be more definite and constant. An animal diet tends to increase the whole amount of solid matter, and particularly to augment the proportion of red corpuscles with hæmoglobin, extractives and salts, especially the phosphate and salts of potassium. On the other hand, a vegetable diet tends to lower the whole amount of solid matter, occasioning a marked reduction in the corpuscles, whilst it seems rather to increase the albumin, fats, sugars, calcareous and magnesian salts; thus showing that the decrease in the corpuscles is not due to a deficiency in the azotized pabulum, but depends on some other condition. The development of fibrin appears to take place at least as readily on the vegetable, as on the animal regimen. Hence we see what may, and what may not, be effected in the treatment of disease by the adoption of a particular dietetic system; for we may promote or retard the development of the red corpuscles by the employment of an animal or a vegetable regimen, but can make little or no impression upon the fibrin.*

197. The effects of *Loss of Blood* and of Abstinence are very similar in their nature. Almost as soon as the stream begins to flow from a wounded vessel, there seems to be a transudation of watery fluid from the tissues into the current of blood; for this undergoes a rapid diminution in density, so that the portion last drawn is of lower specific gravity, and contains a considerably smaller amount of solid matter than that which first issued. The principal diminution occurs in the proportion of red corpuscles; the amount of fibrin, albumin, extractive and saline matters and fat being only slightly affected.† We shall find, indeed, that in inflammatory diseases the amount of fibrin undergoes an extraordinary increase, which is not checked in the slightest appreciable degree by the most copious venesection. Considerable losses of blood are soon repaired, and it is remarkable that after very considerable losses of blood a decided increase shows itself in the proportion of Colourless corpuscles, not only *relatively* (as to the red) but *absolutely;* so that in the blood of a horse from which 50 lbs. have been previously abstracted, the coloured and the colourless corpuscles appear to exist in equal numbers.‡

198. *Pneumatology of the Blood.*—The Gases contained in the blood principally consist of Oxygen and Carbonic acid, the former being chiefly combined with the red corpuscles, the latter wholly with the saline constituents of the plasma. A small proportion of Nitrogen and traces of Ammonia are, however, constantly present. The absolute as well as the relative proportion of these gases differs, not only with the part of the system and the vessel from which the blood is drawn, but also with the globular richness of the blood,§ and to a remarkable extent with the mode of analysis adopted.‖ The mean amount

§ See Mathieu and D'Urbain, "Archiv de Physiol.," 1871–72, p. 14.

‖ Thus the arterial blood of different dogs has been found by different observers to yield

of O in the arterial blood of a healthy dog is 22·2 vol. per cent., of CO_2 34·3 vol. per cent., and of N 1·8 vol. per cent., making a total of 58·3 vol. of gas in 100 vol. of blood. Venous blood in becoming arterial may absorb from 4 to 20 vol. per cent. of oxygen, and at the same time part with from 3 to 13 vol. per cent. of carbonic acid. Under ordinary circumstances it probably gains about 5 or 6 vol. per cent. of oxygen, and parts with about the same quantity of carbonic acid gas, the nitrogen remaining unchanged. There is perhaps a slight diminution in the quantity of O, and increase in the quantity of CO_2, as the blood passes from the larger vessels towards the capillaries, and about 1 per cent. of oxygen disappears from the blood in the course of the first minute after withdrawal from the body, its alkalinity simultaneously diminishing.* From the results of numerous recent researches, the conclusion may be drawn, that the affinity or capacity of absorption of the blood for both oxygen and carbonic acid gases at least, is peculiar, follows laws of its own, and differs materially from that of other liquids. In the case of Oxygen, if we compare it with water, we find that the coefficient of absorption of water for oxygen gas at 0° C. temp. and 760 mm. pressure is 0·04115. If the coefficient of absorption of blood for oxygen were the same, it would only absorb 0·86 vol. per cent. at 0° C., and still less of course at its ordinary temperature of 36° or 38° C., whereas it is known to be capable of absorbing at least 25·4 vol. per cent. at this temperature and at ordinary pressure. This remarkable power is due to the strong affinity for oxygen possessed by hæmoglobin, with which substance nearly the whole of the oxygen contained in the blood is combined to form oxyhæmoglobin. The hæmoglobin in arterial blood is almost saturated with O, whilst in venous blood a variable proportion of the oxyhæmoglobin exists in the reduced condition of hæmoglobin. If, as not unfrequently happens, 100 c.c. of blood contain 14 grammes of oxyhæmoglobin, 23·43 vols. per cent. of O can be extracted from it by means of the mercurial pump, or about 9-10ths of the amount required for its saturation,† and we may even, as Gréhant has shown, conversely regard the amount of oxygen capable of being extracted from blood as a measure of the quantity of hæmoglobin it contains—167·39 c.c. of oxygen at 0° C. and 760 mm. pressure representing 100 grammes of hæmoglobin.‡ The tension of the oxygen in arterial blood under normal conditions is equivalent to an O pressure of 78·7 mm. Hg, which is about one-half of the O partial pressure in the atmosphere at 0° C.§ The serum, as might be expected, contains very little oxygen; the gases of this fluid, according to Pflüger,‖ containing only 0·26 vol. per cent. O with 2·24 N and 35·26 vol. per cent. CO_2. The difference in the amount of oxygen absorbed by the blood in an animal exposed to high pressure from the normal amount is not very great. Thus, Paul Bert found that the blood of a dog contained, at ordinary pressure, 20·2 vol. per cent. of oxygen. When the animal was subjected to a pressure of five and a half atmospheres it was 23·7 vol. per cent., and under a pressure of ten atmospheres the amount had only increased to 24·7 vol. per cent. It would seem that there is a point of saturation of the hæmoglobin which is attained at low pressures, after which the blood

in some instances as small a quantity as 10·3 vol. per cent. of oxygen, and in others as much as 25·4 vol. per cent. The amount of carbonic acid has been found to be as low as 35 and as high as 45·6 vol. per cent., whilst the amount of nitrogen varies from 1·22 to 5·96 vol. per cent. In like manner the proportion of O in venous blood has been observed to vary from 5·5 to 16·5 vol. per cent., of CO_2 from 39 to 52 vol. per cent., and of nitrogen from 1·25 to 4 vol. per cent.

only takes up more oxygen through the plasma, in accordance with the law of Dalton. The importance of the absorption of oxygen being dependent upon chemical affinity, and not simply upon pressure, is sufficiently obvious; since by securing the introduction of a definite proportion of this gas it enables animal life to be maintained without difficulty at all altitudes except the most extreme. Bert* found that when oxygen reaches the proportion of 28-30 vols. in 100 vols. of arterial blood in a dog the animal is seized with convulsions, while a proportion of 35 vols. proves fatal.

199. And so again with carbonic acid gas, whilst 100 vol. of water will absorb about 100 vol. at ordinary temperature and pressure, Meyer† found that 100 vol. of fresh defibrinated blood would take up 178·3 vol. of this gas at 48° F., the quantity increasing, though not in direct proportion, with the pressure. P. Bert, however, found that exposure of a living animal to an augmentation of pressure, even up to ten atmospheres, does not materially influence the amount of CO_2 contained in the blood; in fact, with high pressures, if the original proportion of CO_2 in the blood surpassed 38 vol. per cent., the amount actually diminished, a circumstance that does not admit of ready explanation. The tension of the CO_2 in ordinary air amounts to 0·38 mm., corresponding to 0·05 per cent. by volume; but in arterial blood it amounts on an average to 21 mm.—*i.e.*, to the tension of the gas in an atmosphere containing 2·8 per cent.; and in venous blood to 41 mm., or to the tension of the gas in an atmosphere containing 5·4 per cent.‡ It is very evident, then, that the absorption of this gas also does not take place in accordance with the ordinary law established by Dalton and Henry, but that chemical affinity must come into play; and the general results of recent inquiry shows both the blood-corpuscles and the plasma or serum contain CO_2 in such loose combination that it is given off, in part at least, in the vacuum of a mercurial pump; the serum retaining it more strongly than the red blood-corpuscles. The addition of an acid causes the elimination of a further quantity. Thus Pflüger, from a very pure specimen of serum, obtained 35·2 vol. per cent. of CO_2 on exposure to a vacuum, and an additional 9·3 vol. per cent. on admixture of phosphoric acid. The red corpuscles are capable of acting like an acid upon the serum, and effecting the expulsion of its CO_2, and the action is more energetic in proportion to the amount of oxyhæmoglobin they contain. Even the albumins of the serum appear to possess a similar power, and to act like an acid in expelling CO_2 *in vacuo*. It has been suggested that the CO_2 is in combination in the serum with the carbonate and phosphate of soda,§ since dilute solutions of these salts in water increase its absorption power for CO_2; in the former case a bicarbonate, and in the latter a peculiar double salt $PO_3 + Na_2 + CO_2$, being formed; but Sertoli‖ has shown that the amount of the phosphates in the blood is insufficient. As regards Nitrogen, the coefficient of absorption of water for it at 0° C. and 760 mm. pressure is 0·020316, and 100 vol. of water would therefore absorb 1·608 vol. of N.; and blood seems to follow this law, the average proportion being 1·8. The amount which the blood contains in the living animal is essentially dependent

on the pressure to which the animal is exposed, though it does not precisely follow the law of Dalton, a smaller quantity being absorbed under increased pressure than that law requires. Thus, Paul Bert* found that exposure to 10 atmospheres augmented the amount of N from 2·2 vol. per cent., which was about the normal proportion, to 11·3 vol. per cent. only, whilst if Dalton's law had been followed 22 vol. per cent. should have been absorbed.

200. Besides the differences above described in the proportion of the gases contained in arterial and venous blood, there are several other points which are deserving of notice. Thus, the temperature of arterial blood is usually regarded as a trifle lower in temperature than venous. Its colour is brighter and monochroic, it coagulates rapidly; the number of corpuscles and the quantity of water, fibrin and salts is greater, whilst that of fat is less. Venous blood, on the other hand, is warmer, darker red, dichroic, coagulates more slowly; the number of corpuscles and the quantity of fat is greater, and that of water, fibrin and salts less. The experiments of Dr. Gairdner† seem to show that increase in the relative proportion of oxygen in the blood increases the proportion of fibrin that may be obtained from it, thus the arterial blood of six healthy rabbits furnished the following mean per-centage results:—Fibrin 1·65, Corpuscles 82·35, Albumin 46·30. On the other hand, the analysis of the blood of three individuals which had been made to respire pure oxygen for half an hour, gave the following as the proportions of its components:—Fibrin 2·40, Corpuscles 69·56, Albumin 40·23. It is further stated by Dr. Gairdner,‡ that a rabbit having been kept for half an hour under the influence of an electro-magnetic current between the chest and spine, which produced a great acceleration in the respiratory movements, its blood was found to contain as much as 2·9 parts of fibrin in 1000.§—The larger quantity of fibrin in arterial blood of itself renders its coagulum firmer; but independently of this there would seem to be a difference in the quality of the fibrin, which when separated by stirring or whipping, is more tenacious and compact in arterial than in venous blood. The varying circumstances under which either arterial or venous blood may be at one time dark and at another scarlet in colour, were very fully discussed by Wells‖ and Bernard.¶ The latter observes that in the Fœtus, and in the asphyxiated animal, the blood is everywhere dark or venous. On the contrary, during sleep, in the hibernants during the period of repose, and in animals dying by anæmia, the blood is everywhere scarlet or arterial. With high temperatures of the surrounding medium, whether this be air or water, there is little difference in the colour of the two kinds of blood, the arterial being less and the venous more florid than usual.** The difference between them is, on the other hand, best marked in cold weather. The Blood contained in the veins of muscles is dark, and always of a deeper shade in proportion to the energy and duration of the previous muscular contraction, whilst that returning from the glands is always brighter in proportion to the activity with which secretion is being performed; and in the latter instance, with the alteration in colour, the amount of fibrin is found to

* "Centralblatt f. d. Med. Wiss.," 1868, No. 10.

be diminished, or so modified as to form a softer clot, from which a larger quantity of serum separates. The variations which occur in the gases of venous blood returning from muscles at rest and in action, as compared with the arterial blood of the same animal, are well shown in the following results obtained by Sczelkow,* where A indicates Arterial blood, MR the blood returning from muscles at rest, and MA that returning from muscles in action:—

Total Gas.		O	N	Free CO_2	Combined CO_2	Total CO_2
A	43·515	17·334	1·636	24·204	0·341	34·545
MR	40·450	7·5	1·364	31·036	0·550	31·586
MA	37·069	1·265	0·923	34·443	0·438	34·881

In other experiments Sczelkow found that the venous blood returning from muscles at rest contained on the average 6·71 per cent. more carbonic acid and 9 per cent. less oxygen than arterial blood, whilst that returning from muscles in action contained an excess of 10·79 per cent. of carbonic acid, and a deficit of from 12 to 14 or even 16 per cent. of oxygen; and similar results were obtained by Bernard.† It is remarkable that if the dark-coloured clot of ordinary venous blood be immersed in the serum of the scarlet venous blood, it rapidly assumes a brighter tint, and conversely the clot of scarlet venous blood changes to a dark colour when immersed in the serum of deeply-coloured venous blood; from which we may conclude that the primary changes are effected upon the Liquor Sanguinis, and not upon the corpuscles. The influence of the Nervous System in inducing alterations in the colour of the blood returning from the salivary glands has already been pointed out (§ 106).

201. Although but little difference except as regards the relative proportion of oxygen and carbonic acid gases present can be detected between samples of blood drawn from various parts of the *Arterial* system of the same animal, very important variations exist, as might be expected, in the composition of the blood drawn from the several parts of the *Venous* system; since the changes to which it has been subjected in the several organs through which it has passed, are of a very diversified character. The blood of the Vena Portæ, for example, differs considerably from the blood of the Hepatic vein, and both of these differ from the blood of the Jugular. So, again, the blood of the Splenic as well as that of the Renal vein differs from all the preceding. The most important and best-established of these diversities will now be enumerated. The best as well as the most recent comparison between the blood of the vena portæ and that of the vena hepatica has been made by Drosdoff,‡ under Hoppe-Seyler's direction. The animals employed were dogs which were fed with meat, bread, and milk three or four hours before the blood was withdrawn. No attempt was made to estimate the amount of fibrin, and the coagulation of the blood was not awaited, but it was immediately whipped, and watery, ethereal and alcoholic extracts made of the remainder. Constant differences were observed, of which some only admit of explanation on the supposition that they are the result of changes taking place in the liver, whilst the cause of others is more doubtful. In four carefully-conducted

† "Leçons," vol. ii. 1859, p. 435.

‡ "Zeits. f. Phys. Chemie," 1878, p. 233.

analyses the blood of the vena portæ was invariably richer in solid constituents than that of the hepatic vein, the difference in this and other respects being shown in the following Table :—

	Portal Vein.	Hepatic Vein.
Water	725·8	743·3
Solids	274·2	256·6
Hæmoglobin, albumins, and insoluble salts...	251·7	237·8
Cholesterin	2·6	2·7
Lecithin	2·4	2·9
Fats	5·7	0·9
Alcoholic extractives	1·2	1·3
Water extractives	5·0	5·6

The excess of fats in the portal vein is remarkable. In speaking of the composition of the blood of the *Vena Portæ*, it must be remembered that this consists of two very distinct factors—namely, the blood of the Gastric and Mesenteric veins, and the blood of the Splenic vein; the former having been altered by the introduction of solid and liquid alimentary matters, and the latter by its circulation through the spleen. These, therefore, ought to be separately studied; and this has been done by M. Jules Béclard.* The characters of the blood returning by the *Gastric* and *Mesenteric* veins from the walls of the alimentary canal are, of course, affected by the stage of the digestive process, and by the nature and amount of the absorbable matters. As compared with the ordinary venous blood, the total quantity of its solid constituents is lowered during the early part of the digestive process, by the dilution it suffers through the imbibition of liquid; and this diminution is especially remarkable in the corpuscles, the relative proportion of albumin being increased by the introduction of new albuminous matter from the food. Towards the conclusion of the digestive process, however, the blood of the mesenteric veins gradually comes to present the ordinary proportions of these two components; and in an animal that has been subjected to long abstinence, it does not differ from that of the venous system in general. The quantity of extractive is usually increased; and in this part of the blood it must be, that sugar, dextrin, gelatin, and other soluble organic matters that are taken into circulation are contained. Some of these have in fact been detected in it.† The fibrin of the blood of the mesenteric veins appears to be less perfectly elaborated than that of the blood in general; for the blood of the mesenteric veins coagulates less firmly (having been erroneously asserted by some not to coagulate at all); and its fibrin, when separated by stirring, shows a marked deficiency in tenacity, and liquefies completely in the course of a few hours. A part of the albuminous constituent of this blood does not present the characters of true albumin, for it is not precipitated by heat or by nitric acid, and the precipitate thrown down by alcohol is redissolved by water; like albumin, however, it is precipitated by the metallic salts, creasote, and tannin. This substance, which has been distinguished by M. Mialhe as *albuminose*, is in fact a peptone, differing from true albumin in the facility with which it traverses organic membranes; for these resist the passage of albumin, while they are freely transuded by peptone. And it is affirmed by M. Mialhe that the want of that conversion of albuminose into albumin, which ought to take place as part of the assimilating process, is one cause of the readiness with which albuminous matter transudes from the blood in albuminuria and

* See his Memoir in the "Arch. Gén. de Méd.," 4e série, tom. xviii. p. 322, *et seq.*; and his edition of his father's "Elémens d'Anatomie Générale," pp. 265, 266.

† See the Researches of MM. Bouchardat and Sandras in the "Supplément à l'Annuaire de Thérapeutique," 1846.

in dropsies; this albuminous matter frequently having rather the characters of albuminose, than those of true albumin.*

202. The Splenic blood is remarkable for the marked decrease it presents in the amount of solid matter it contains; the average of twelve experiments giving only 187·1 per 1000 of solid constituents in the splenic blood, whilst the arterial blood of the same animals contained 239 parts, and the jugular venous blood 201 parts.† The decrease depends upon the diminished proportion of *red* corpuscles. The albumin and fibrin, on the other hand, with the white corpuscles, are usually more or less increased in their relative proportions, the fibrin having been found in amounts varying from 2·5 to 11·53 parts in 1000, and coagulation having been noticed to recur when the blood had already been freed from the fibrin by whipping. Hirt‡ counted 1 colourless to 2179 coloured corpuscles in the blood of the splenic artery, but 1 colourless to 60 coloured in that of the splenic vein. The red corpuscles sometimes present crystals in their interior. M. Malassez§ remarks that the corpuscles are *really* more abundant in the blood of the splenic vein, and fewer in that of the hepatic vein, because they are formed in the spleen and destroyed in the liver. They are *apparently* diminished in the mesenteric veins during digestion, owing to absorption of fluid; and apparently increased in the blood of the skin, glands and tissues generally, owing to the exosmose of the fluid parts. It cannot be doubted that when the secretion of urine is proceeding with rapidity, the blood of the *Renal vein* must contain a smaller proportion of water than that of the renal artery, and that the quantity of salts also must be diminished; since a separation of these ingredients takes place in the passage of the blood through the renal capillaries. So far as regards the quantity of water this *à priori* conclusion has been confirmed by the analysis of Simon, who found 790 parts of water in 1000 of blood drawn from the renal artery, and only 778 in blood drawn from the renal vein of the same animal.‖ And Picard¶ found in the renal arterial blood of two dogs 0·0365 and 0·04 per cent. of Urea, whilst in the venous blood returning from the kidneys the proportion was 0·0186 and 0·02 per cent. Poisseuille and Gobley,** however, did not find the difference so well-marked or constant.

203. *Alterations in the Composition of the Blood in Disease.*—Under this head it is intended here to consider, not the state of the Blood in every principal type of disease (which it is the duty of the Pathologist to investigate), but the most important facts which the study of its morbid conditions has afforded, towards the determination of the conditions under which decided variations take place in the quantity or quality of its principal components, and of the effects which those variations produce upon the system at large. Many analyses have been made by excellent observers;†† but in consequence of the variations in the mode of analysis pursued, the results can only be given in general terms.

204. The first of these components whose variations we shall consider, is *Fibrin*: the estimate of which, however, is open to an important fallacy, that

†† See Andral and Gavarret, "Essai d'Hæmatologie Pathologique;" Becquerel and Rodier, "Recherches sur la Composition du Sang," &c.

has not been sufficiently guarded against—namely, the admixture of the Colourless corpuscles. "These," as Sir James Paget correctly remarks, "cannot, by any mode of analysis yet invented, be separated from the fibrin of mammalian blood; their composition is unknown, but their weight is always included in the estimate of the fibrin. In health they may, perhaps, add too little to its weight to merit consideration; but in many diseases, especially in inflammatory and other blood-diseases in which the fibrin is said to be increased, these corpuscles become so numerous that a large proportion of the supposed increase of the fibrin must be due to their being weighed with it. On this account all the statements respecting the increase of fibrin in certain diseases need revision."* In the results of the analyses now to be stated, it must be borne in mind that the term 'fibrin' really designates the 'colourless coagulum' of spontaneous formation, whatever may be its composition. The following may be considered as the normal range of variation for the principal constituents of the blood in health, according to the mode of estimating them pursued by MM. Andral and Gavarret:—

Fibrin	from	2	to	3½	parts per 1000
Red corpuscles . .	„	110	„	152	„ „
Solids of serum . .	„	72	„	88	„ „
Water	„	760	„	815	„ „

205. The most important fact substantiated by Andral, is one that had been previously suspected,—the invariable increase in the quantity of Fibrin during acute Inflammatory affections, as pleurisy and pneumonia, the increase being strictly proportional to the intensity of the inflammation, and to the degree of symptomatic fever accompanying it. "The augmentation of the quantity of Fibrin is so certain a sign of Inflammation, that, if we find more than 5 parts of fibrin in 1000, in the course of any disease, we may positively affirm that some local inflammation exists." The average proportion of Fibrin in inflammation may be estimated at 7; the minimum at 5; the maximum at 13·3. The greatest augmentation is seen in Pneumonia and Acute Rheumatism. Such blood in general coagulates slowly.† An increase is also commonly observable during the advanced state of Phthisis, in spite of the deterioration which the blood must then have undergone, and this is probably dependent upon the development of local inflammation around the tubercular deposits. In Continued and Typhoid Fevers, whilst the proportion of Corpuscles is commonly increased, there is a decrease in the proportion of Fibrin, especially in the early stage; though the usual augmentation will take place if any local inflammation occurs. It appears from the experiments of Magendie, that one of the effects of a diminution in the proportion of Fibrin is a tendency to the occurrence of Hæmorrhage or of Congestion, either in the parenchymatous tissue or on the surface of membranes; and these conditions are well known to constitute common complications, not only of febrile diseases, but also of Apoplexy and Purpura hæmorrhagica, in both of which there is a marked deficiency of Fibrin. It has been asserted that the proportion of Fibrin is diminished in Scurvy; but this, from the analyses of MM. Becquerel and Rodier, Chatin and Bouvier,‡ and Mr. G. Busk,§ appears not

* Morrant Baker's "Handbook of Physiology."

† The white fibrinous clots found after death in the heart and large arteries in various diseases appear to owe their origin to the slight disposition of the blood in these cases to coagulate, thus affording time for the sinking or separation of the red corpuscles. Mayer has augmented the amount of fibrin in the blood of dogs to nearly double its normal amount by repeated bleedings, repeated at stated intervals (quoted in Brücke's "Vorlesungen," 1874, p. 117).

‡ "Journ. de Chemie Médicale," Mars, 1848.

§ "Library of Medicine," vol. v. p. 90. See also Chalvet, "Union Médicale," 1871, p. 525.

to be the case, the proportion of fibrin being rather above than below the normal average. In Cholera, however, a reduction in the coagulable element of the blood seems to be an almost constant occurrence; and in some instances, the blood, although loaded with solid matter, has scarcely coagulated at all. Of the blood drawn during life, it has been observed that the clot is loose and grumous, often not shrinking and expelling serum; and that this change presents itself in a degree corresponding to the severity and advanced stage of the disease. And when the blood has been removed from the body after death, the clots have been found loose and fragile in texture, sometimes almost semi-fluid.* How far the so-called exudation found in an inflamed part is dependent upon the accumulation of the white corpuscles on the exterior of the vessels, as described by Waller and Cohnheim, cannot as yet be stated with certainty.

206. The amount of *Red Corpuscles* seems to be subject to great variation within the limits of ordinary health. It may even form a racial characteristic, for Mr. Bakewell† states that he was able to distinguish the Mahommedan from the Hindoo by the proportion of corpuscles contained in their blood, and both of these races readily from the negro, the blood in the latter race being very highly corpusculated. In the condition which is ordinarily termed a highly sanguineous temperament, or Plethora, it is chiefly the entire mass of the blood that undergoes an increase; but whatever excess there may be in the proportion of its solid constituents, this affects the corpuscles rather than the fibrin, the proportion of these, according to Mantegazza,‡ rising from 5,000,000, which is the normal amount, to 5,500,000, in a cubic millimetre. Plethoric persons are not more prone to inflammation than are those of weaker constitution; but they are liable to congestion, especially of the brain, and to apoplexy or other hæmorrhage. The effect of bleeding in diminishing this tendency is now intelligible, since we know that loss of blood reduces the proportion of corpuscles. On the other hand, in that temperament§ which, when exaggerated, becomes anæmia, there is a marked diminution of the corpuscles, the number contained in a cubic millimetre falling from 5,000,000, which is the normal amount, to about 2,000,000. This temperament may lead, on the one hand, to chlorosis, in which the proportion of red corpuscles, and especially of their hæmoglobin contents,‖ are diminished, a condition of the system which is singularly improved by the remedial employment of Iron;¶ and, on the

* See Dr. Parkes' "Researches into the Pathology and Treatment of the Asiatic or Algide Cholera," pp. 32, 73.

† "Med. Times and Gazette," Nov. 1872, p. 514. Also a Paper read before the Anthropological Society.

‡ "Gaz. Med. Ital." 1865, Nos. 23 and 25.

§ The term *lymphatic* has been applied to this temperament; by which term was meant a predominance of lymph in the absorbent vessels.

‖ See Hayem, "Recherches sur l'Anat. Norm. et Path. du Sang," Paris, 1878; Leichtenstein "Untersuch. üb. die Hæmoglobingehalt d. Blutes," Leipzig, Vogel, 1878.

¶ The records of Medicine scarcely furnish a more notable example of the pernicious influence of theories founded upon a shallow Empiricism, and of the superiority of a Rational practice, based on a knowledge of the real facts of the case, than is afforded by the contrast between the former and the present treatment of *Chlorosis*. Whilst the notion prevailed that the 'buffy coat' is a sign of Inflammation, and that the most potent remedy for Inflammation is loss of blood, patients already reduced to a state of anæmia, who complained of pain in the left hypochondrium, palpitations, &c., were bled over and over again, every withdrawal of blood of course seriously increasing the mischief, by producing a further reduction in the proportion of red corpuscles. The Author well remembers that, when a pupil in the Bristol Infirmary in the years 1833–34, he was repeatedly directed by the estimable Senior Physician (long since dead) to draw eight, ten, or twelve ounces of blood from patients in this condition; and that the crassamentum, after coagulation, often resembled a small island floating in an ocean of serum. Yet, because this minute clot exhibited the buffy coat, the bleeding was considered to be 'orthodox' practice, and the obstinacy of the symptoms

other, to Scrofula, in which a diminution of Corpuscles coexists with a deficiency in the amount or in the degree of elaboration of the Fibrin. A similar deficiency in the proportion of red corpuscles has been observed by Andral in other cachectic states induced by disease, as in Diabetes Mellitus, Aneurismal Dilatation of the Heart producing Dropsy, and in Cachexia Saturnina. It occurs also in Scurvy, and in the advanced stages of Albuminuria; and Dr. Williams* has observed extraordinary destruction of the blood-discs in a case of malignant scarlatina with purpura; and has met with indications of a partial destruction of them in acute purpura connected with jaundice, and in cases of functional derangement of the liver.

207. A marked increase in the proportion of the *Colourless Corpuscles* has been frequently observed in the blood of Inflammatory subjects; this increase is not, however, so characteristic of the Inflammatory state as some have supposed; for it is by no means constant in that condition, and is frequently seen in very different states of the system.†—Attention has recently been drawn by Prof. J. H. Bennett‡ to a condition of the blood which is especially characterized by a marked excess of these bodies, and which he has designated by the term *Leucocythæmia* (white-cell blood). This condition has been detected in the blood of a considerable number of individuals suffering under diseases (most commonly, enlargement) of the Spleen, Liver, and Lymphatic Glands, either separately or in conjunction; but it has not yet been determined how far it is constantly associated with any of these abnormal conditions. In all cases in which such blood has been analyzed, its specific gravity has been found very low, and the total amount of corpuscles small; but the fibrin is almost invariably above the average, having in one instance risen to 7·08.

208. The quantity of *Albumin* in the blood seems to vary less than that of most of its other constituents. The proportion which it bears to the water of the serum is, of course, elevated by anything which diminishes the latter; and thus we find it high in cholera after profuse discharges of fluid from the intestinal canal, and in other cases in which there has been an unusual drain upon the liquid part of the blood, provided that the albumin do not pass off with it, as sometimes happens. Where some special cause is in operation, which favours the escape of the albumin from the circulating current (as happens in various forms of albuminuria, but especially in the advanced stage of 'Bright's disease'), the amount of albumin in the serum is reduced below the normal standard. Thus, Dr. Christison found the entire solids of the serum to be reduced in some instances to 55 or even 52 parts in 1000, his estimate of their normal amount being 83·4; and he found the specific gravity of the serum to fall as low as 1020 or even 1019, the normal standard being from 1027 to 1031. According to Andral, the diminution in the amount of albumin in the serum is exactly proportional to the quantity contained in the urine.§ The propor-

was attributed to the severity of the disease. If M. Andral had made no other contribution to Medical Science than the demonstration of the real nature of this condition of the blood, and of the influence of further depletion in promoting it, he would have rendered a most essential service to the multitude of females who are unfortunate enough to suffer from this kind of deterioration of their vital fluid.

* "Principles of Medicine," 2nd edit. p. 115.

† As in Scurvy. See Laboulbène, "La Revue Scient.," sér. ii. an. 1, p. 43, 1871.

‡ See his successive Papers in the "Edinb. Monthly Journal" for 1851, his Treatise "On Leucocythæmia," and his Clin. Lectures "On the Principles and Practice of Med.," 4th edit. 1865, p. 867, *et seq.*

§ A case is related by Andral, under this head, which affords an interesting exemplification of the general facts that have been attained by his investigations. A woman who had been suffering from Erysipelas of the face, and had lost blood both by venesection and by leeches, became the subject of Albuminuria. The blood drawn at this time exhibited a considerable

tion of albumin is not diminished in scurvy (Chalvet). The proportion of *fatty* matter in the serum, and especially of the cholesterin, has been found by MM. Becquerel and Rodier to undergo an increase at the commencement of most acute diseases; and they have also observed an increase of fat, and especially of cholesterin, in chronic diseases of the liver, in Bright's disease of the kidney, and in tuberculosis. The quantity of fat in the blood sometimes undergoes such an augmentation as to give to the serum a constant 'milkiness.' This has been observed by Marcet in a case of diabetes, by Traill in hepatitis, by Christison in dropsy, icterus, and nephritis, by Zanarelli in pneumonia, and by Sion in mammary abscess. In Dr. Sion's case, the blood itself was quite milky; it underwent no coagulation; and only a very small quantity of colouring matter was deposited, when it was allowed to stand. This blood was found by Lecanu to contain 206 parts of solid constituents in 1000; but of these no less than 117 parts were fat, the remainder consisting of albumin (64 parts), and of extractive and salts (25 parts).* No fibrin could be found, and the quantity of hæmoglobin was inappreciable.† Such a fluid must be considered rather as chyle than as blood; and in the entire absence of coagulating power, corresponds rather with chyle when first absorbed, than with that which is usually transmitted by the thoracic duct.—Little is known with certainty regarding the variations of the *alkaline salts* in the blood in different diseases. The analyses which have been made, however, are considered by Prof. Lehmann‡ to indicate that in very severe inflammations they are greatly diminished; whilst they are much increased in the acute exanthemata and in typhus, in dysentery, Bright's disease, and all forms of dropsy and hydræmia; and are often doubled in quantity in diseases depending upon malarious influences, such as endemic dysentery, malignant forms of intermittent fever, &c. Although a large quantity of saline matter usually passes off from the blood in cholera, yet the proportion of water discharged is so much greater, that, as appears from the analysis of Dr. Garrod, the per-centage of salts in the blood is rather increased than diminished.§ The proportion of *water* in the blood will, of course, vary reciprocally with that of the solid constituents; and will be specially augmented when there is a marked diminution in the amount of red corpuscles.

209. That the Blood is subject to a great variety of other morbid alterations,

diminution in the proportion of the Red Corpuscles, as well as of Albumin,—a fact which the previous loss of blood fully accounted for. After a short period, during which she had been allowed a fuller diet, another experimental bleeding exhibited an increase in the proportion of those Corpuscles. Some time afterwards, when the Albumin had disappeared from the Urine, some more blood was drawn; and it was then observed that the Albumin of the Serum had returned to its due proportion, but that the Corpuscles had again diminished, whilst there was a marked increase in the quantity of Fibrin. This alteration was fully accounted for by the fact that, in the interval, several lymphatic ganglia in the neck had been inflamed and had suppurated; and that the patient had been again placed on very low diet. "Thus," observes Andral, "we were enabled to give a complete explanation of the remarkable oscillations which were presented in the proportion of the different elements of the blood, drawn at three different times from the same individual; and thus it is that the more extended are our inquiries, the more easy does it become to refer to general principles the causes of all those changes in the composition of the blood, which, from the frequency and rapidity with which they occur, seem at first sight to baffle all rules, and to take place, as it were, at random. In the midst of this apparent disorder there is but the fulfilment of *laws;* and, in order to obtain these, it is only necessary to strip the phenomena of their complications, and reduce them to their simplest form."

* See also a case by Speck, "Archiv f. wiss. Heilk.," 1864, p. 232.

† This remarkable case is cited in Simon's "Animal Chemistry," vol. i. p. 333, from the "Lancette Française," 1835, No. 49.

‡ "Physiological Chemistry" (Cavendish Society's ed.), vol. ii. p. 262.

§ "London Journal of Medicine," May, 1849.

which are sometimes the causes, and sometimes the results of Disease, cannot be for a moment doubted. But our knowledge of the nature of these changes is as yet very insufficient.* The great amount of attention which is being directed by Chemists and Pathologists to the subject, however, will doubtless ere long produce some important results.—Among the most frequent causes of depravation in the character of this fluid, we must undoubtedly rank the retention, in the Circulating current, of matters which ought to be removed by the Excretory processes. We shall hereafter see that a total interruption to the excretion of Carbonic Acid by the lungs will occasion death in the course of a very few minutes; and even when only a slight impediment is offered to the elimination of the carbonic acid, so that the quantity of it always contained in arterial blood is augmented to but a small degree, a feeling of discomfort and oppression, increasing with the duration of the interruption, is speedily produced. The results of the retention of the materials of the Biliary and Urinary excretions will be hereafter considered (CHAP. XI.); and at present it will be only remarked that such retention is a most fertile source of slight disorders of the system, that it is largely concerned in producing many severe diseases, and that, if complete, it will most certainly and rapidly bring about a fatal result.

3. *Of the Vital Properties of the Blood, and its relations to the Living Organism.*

210. It cannot be doubted that the perfect and regular performance of the various actions to which the Blood is subservient is dependent upon the admixture of its principal components in their due proportions, and upon its freedom from deleterious matters whether formed within the system, or introduced into the circulating current from without. And it is not difficult to

* It seems not improbable that the phenomena of disease are sometimes caused by, though perhaps in other instances they may be only associated with, the development of living organisms in the blood. Thus extremely fine, moving thread-like bodies resembling spirillum, have been observed by Obermeier ("Centralblatt," 1873, p. 145) in the blood of patients suffering from recurrent fever, shortly before or during the crisis, but their nature is unknown. See also Burdon Sanderson, "Brit. Med. Journ.," vol. ii. 1877, vol. i. 1878. Nedvetski (idem, 1872, p. 234) has seen moving particles, apparently derived from the white corpuscles, and bacteridia in the blood of choleraic patients. Nepveu ("Gaz. Med. de Paris," 1872, No. 3) has noticed bacteria in cases of erysipelas. Lewis (Pamphlet, 1872, "Lancet," 1873, 1, 446) has described a peculiar kind of Filaria, as being constantly present in large numbers in the blood of patients (in India) suffering from chyluria; Riess (Reichert's "Archiv," 1872, p. 237), bright granules in scarlet fever; Birsch-Hirschfeld ("Archiv d. Heilkunde," xiii. 1872, p. 38), micrococci in pyæmia and puerperal fever; Hüter ("Centralblatt," 1868, p. 177), similar forms in diphtheritis. See also Orth, "Archiv d. Heilkunde," 1872, xiii. p. 265, and Hiller, "Centralblatt," 1874, p. 833. In the "Biennial Retrospect of Physiology," of the New Syd. Soc. for 1875, several other references will be found. Considerable interest attaches to a statement recently made by Lostorfer ("Wien. Med. Jahrb.," 1872, Heft i. p. 96), and confirmed by Stricker, though vehemently denied by others, that the blood of syphilitic patients can be recognised by the presence of small bright bodies, which present Brunonian movements, and in the course of a week after removal from the body, enlarge, sprout, become vacuolated, and die. Lostorfer's statements have been partially corroborated by Biesiadecki, who, however, regards the bright particles as paraglobulin ("Untersuch. aus dem Path.-Anatom. Institute in Krakau," Vienna, 1872) precipitated by carbonic acid developed during the decomposition of the blood. Such particles are present in small numbers in all blood, but are uncommonly abundant in blood preparations from syphilitic patients, either because their blood contains more paraglobulin or less fibrinogenous substance than other blood. See article by Klein in "Lond. Med. Record," April 9, 1873. Halford, "On the Condition of the Blood after Snakebite," 1867, has observed peculiar nucleated cells in the blood after snakebite, which he believes to be derived from germinal matter in the poison of the snake, and to have grown at the expense of the blood.

see how any considerable alteration which affects its *physical* conditions merely, may thereby produce a most serious disturbance in the regularity of the circulation, and in the functions to which it ministers. Thus, it has been shown by the experiments of Poisseuille,* that a certain degree of viscidity is favourable to the motion of liquids through capillary tubes; a thin solution of sugar or gum being found to traverse them more readily than pure water will do. Hence any serious alteration in the proportion of the organic and saline compounds dissolved in the liquor sanguinis, and especially in that of the Fibrin, might be expected to produce obstruction in the capillary circulation, and to favour transudation of the fluid portion of the blood; and the numerous experiments of Magendie (Op. cit.) seem to favour this view, although they are far from manifesting that character for accuracy and discrimination, which would be required to afford an authoritative sanction to it. A much more determinate influence, however, must be exerted upon the Red Corpuscles, by any cause which seriously affects the specific gravity of the liquor sanguinis; and the perfect elaboration of the Albuminous constituent of the serum has been shown to be requisite to prevent it from copiously transuding the membranous walls of the vessels which it traverses.—These and other physical and chemical relations of the blood are quite subordinate to its vital reactions; and it is into them that we have now to inquire.

CHAPTER VIII.

OF THE CIRCULATION OF THE BLOOD.

1. *Of the Circulation in General.*

211. The Circulation of nutritive fluid through the body has for its object, on the one part, to convey to every portion of the organism the materials for its growth and renovation, together with the supply of Oxygen which is requisite for its vital actions (especially for those of the Nervo-Muscular apparatus); and at the same time to carry-off the particles which are set free by the disintegration or 'waste' of the tissues, and which are to be removed from the body by the Excreting processes. Of these processes, the one most constantly in operation, as well as most necessary for the maintenance of the purity of the blood, is the excretion of Carbonic Acid through the Respiratory organs; and this is made subservient to the introduction of Oxygen into the system. In Man, as in other Vertebrated animals, there is a regular and continuous movement of the nutritive fluid through the sanguiferous vessels; and upon the maintenance of this, the activity of all parts of the organism is dependent. In common with Birds and Mammals, again, Man has a Respiratory circulation entirely distinct from the Systemic; all the blood which has returned from the body being transmitted to the lungs, and being brought back to the heart again, before it is sent-forth afresh for the nourishment of the tissues and for the maintenance of their functional activity. The Heart is placed at the junction of these two distinct circulations, which may be likened to the figure 8; and it may be said to be formed by the fusion of two distinct organs, a 'pulmonary' and a 'systemic' heart; for its right and left sides, which are respectively appropriated to these purposes, have no direct commu-

* See M. Magendie's "Leçons sur les Phénomènes Physiques de la Vie," tom. iv. p. 57.

nication with each other (in the perfect adult condition, at least), and seem merely brought together for economy of material.* Each system has its own set of Arteries or efferent vessels, and of Veins or afferent trunks; these communicate at their central extremity by the Heart, and at their peripheral extremity by the Capillary vessels, which are nothing else than the minutest ramifications of the two systems, inosculating into a plexus.—Besides the systemic and pulmonary circulations, however, there is another which is no less distinct, although it has not an impelling organ of its own. This is the 'portal' circulation, which is interposed between the venous trunks of the abdominal viscera and the Vena Cava, for the purpose of distributing that blood through the Liver, in which organ its newly-absorbed materials undergo assimilation, whilst its excrementitious matters are separated by the secreting process. The Vena Portæ, which is formed by the convergence of the gastric, intestinal, splenic, and pancreatic veins, subdivides again like an artery, so as to form a capillary plexus which extends through the whole substance of the liver; and the Hepatic vein, collecting the blood from this plexus, conveys it into the Vena Cava. Thus the *portal* circulation is grafted (so to speak) upon the *general* circulation, in precisely the same mode as the respiratory circulation is grafted upon it in Mollusca and Crustacea; and if the 'sinus' of the Vena Portæ had possessed contractile muscular walls it would have ranked as the proper heart of the portal system. The really arterial character of the Vena Portæ is well shown by comparing it with the Aorta of Fishes; which is formed by the convergence of the Branchial veins, and then distributes the blood which it has received from them to the body generally.

212. That the movement of the Blood through the arterial trunks and the capillary tubes is, in Man, and in other warm-blooded animals, chiefly dependent upon the action of the Heart, there can be no doubt whatever. It can be easily shown by experiment, that if the arterial current be checked, the capillaries will immediately almost entirely cease to deliver the blood into the veins, and the venous circulation will be consequently arrested. And it has also been proved that the usual force of the Heart is sufficient to propel the blood, not only through the arterial tubes, but through the capillaries, into the veins; since even a less force will serve to propel warm water through the vessels of an animal recently dead.† But there are certain "residual phenomena" even in Man, which clearly indicate that this is not the whole truth; for not only is the general current of blood greatly modified in its passage through the circulating system, but there are many variations in its movement, which, being very limited in their extent, cannot be attributed to any central disturbance, and must therefore be dependent on causes purely local. Hence we are led to perceive that forces existing in the Blood-vessels themselves must have a considerable influence in producing both general and local modifications of the effects of the Heart's action. There are also indications of the existence of influences in which the blood-vessels do not partake, arising from those changes occurring between the blood and the tissues, that constitute the processes of Nutrition, Secretion, &c. Of the nature of these influences, and of the degree of their operation, the most correct idea may be obtained by examining the phenomena of the Circulation in those beings, in which the moving power is less concentrated than it is in the higher Animals. Thus we find that in Plants and the lowest animals, as in the earliest embryonic state of

* At an early period of fœtal life, as in the permanent state of the Dugong, the heart is so deeply cleft, from the apex towards the base, as almost to give the idea of two separate organs. † See Dr. Williams's "Principles of Medicine," 2nd edit., p. 185, *note*.

the highest, a movement of nutritious fluid takes place through a system of minute passages or channels excavated in the tissues (representing a *capillary* plexus), without any *vis a tergo* derived from an impelling organ. Ascending a little higher in the series, we meet with a system of vascular *trunks*, distributing the blood to these plexuses, and collecting it again from them; and the walls of these trunks are so far endowed with contractility, as to assist, by a sort of peristaltic movement, in the maintenance of the current through them. Still passing upwards, we find this contractility manifesting itself especially in some limited portion or portions of the vascular system, which execute regular movements of contraction and dilatation; and this tendency to concentration is increasingly observed, until the whole movement is subordinated to the action of a principal propelling organ, the Heart.*

213. The heart is contained in a serous sac named the *Pericardium*, by which its movements are facilitated. This sac is of conical shape with the base downwards, and rests on the diaphragm, to which it is firmly attached. It presents a *visceral* layer, which closely invests the muscular substance of the heart and is continued for some distance over the large vessels; and a *parietal* layer, which is reflected from the vessels and is greatly strengthened by fibrous tissue. The internal and opposed surfaces of the two layers are lined by pavement epithelium; the subserous layer contains a variable amount of fat and numerous lymphatics, in connection with which no stomata have been observed. *Nerves*, proceeding from the right vagus† just below the origin of the recurrent nerve, and from the phrenic, especially from those of the right side, have been traced into the parietal layer of the pericardium. The elaborate dissections of Dr. J. B. Pettigrew‡ have shown that the walls of the ventricles of the heart are composed of a series of seven layers or strata of muscular fibres, of which three are external, the fourth is central, and the remaining three are internal. The direction of the fibres constituting these layers gradually changes from a nearly vertical to a horizontal or transverse one, which is the course pursued by the fourth layer, and from this back again to a nearly vertical one. The fibres composing corresponding external and internal layers, such as layers one and seven, two and six, &c., are continuous in the left ventricle at the left apex, and in the right ventricle in the track for the anterior coronary artery, the fibres of both ventricles being for the most part continuous likewise at the base, forming, therefore, a series of figure-of-8 loops. The outermost fibres of both ventricles, on reaching the apex of the heart, present two bundles, which, curving round in the form of a vortex, or whorl, become continuous with the fibres of the carneæ columnæ and musculi papillares. Only the first and seventh layers are inserted into the auriculo-ventricular rings to which they pass in a direction almost at right angles to their planes. The object of these special arrangements appears to be, as Dr. Hensley§ has pointed out, to enable the muscular walls of the cavities of the heart to expel by their contraction the whole of their contents, whilst the shortening of the several fibres is both uniform in amount and moderate in extent.

214. There are, however, some important differences in the structure and

* See "Princ. of Comp. Phys.," chap. v. A very full and comprehensive account of the circulation and the apparatus by which it is effected in plants, in the lower animals, and in Man, will be found in Dr. J. Bell Pettigrew's work on the "Physiology of the Circulation," 1874.

† Luschka, quoted in Krause's "Histologie," 1876, p. 299, and in Frey's "Histology," Barker's translation, 1874, p. 403.

‡ "Phil. Trans.," part iii. 1864, p. 445.

§ "Journ. of Anat. and Physiology," vol. iv. 1870, p. 83.

functional actions of the two divisions of the Heart, which should be here adverted to.—The walls of the *left* Ventricle are considerably thicker than those of the *right;* and its force of contraction is much greater. The following are the comparative results of M. Bizot's measurements,* taking the average of Males from 16 to 79 years:—

	Base.	Middle.	Apex.
Left Ventricle	$4\frac{1}{6}$ lines	... $5\frac{1}{6}$ lines	... $3\frac{3}{4}$ lines.
Right Ventricle	$1\frac{15}{16}$ lines	... $1\frac{3}{8}$ lines	... $1\frac{1}{30}$ lines.

In the Female, the average thickness is somewhat less. It will be seen that the point of greatest thickness in the *left* Ventricle is near its middle; while in the *right*, it is nearer the base. The thickness of the former goes on increasing during all periods of life, from youth to advanced age; whilst that of the latter is nearly stationary. During pregnancy there is an hypertrophy of the left Ventricle to the extent of 1-4th or even 1-3rd of the original thickness of its walls.† The *left* Auricle is somewhat thicker than the *right;* the average thickness of the former being, according to Bouillaud, a line and a half; whilst that of the latter is only a line. In regard to the relative capacities of the right and left cavities, much difference of opinion has prevailed;† and so much fallacy may arise from the peculiar condition of the animal at the moment of death, that it is almost impossible to make any direct measurement.—The average capacity of the several cavities may, however, be estimated as equal in the full-sized Heart, each holding about five ounces.—The regurgitation of the blood is effectually prevented by *valves* which are situated between the cavities of the auricles and ventricles, and at the commencement of the aorta and pulmonary arteries. The right auriculo-ventricular aperture is guarded by the "tricuspid," and the left by the "mitral" valve; whilst the name "semilunar" valves is applied to those which are situated at the origin of the great arteries. These valves are composed of connective tissue with a layer of elastic tissue, which is a prolongation of the endocardium. The cuspidate valves contain a few striated muscular fibres, some of which run parallel

† Larcher, "Comptes Rendus;" Henle and Meissner's "Bericht," 1857, p 467.

‡ Winslow, Senac, Haller and Lieutaud, Boyer, Bizot and Legallois maintain that the

to the base, whilst others radiate from the fibrous ring.* In the case of the valves of the pulmonary artery they appear to be not quite equal in size, nor are they exactly upon the same plane; when made to act by pouring water into them, and watching them from below, it may be seen, according to Dr. Pettigrew, that the smallest segment, which is situated highest, descends with a spiral movement, and first falls into position; the middle-sized segment, which is placed a little lower, descends in like manner, fixing the first segment by one of its lunulæ or crescentic surfaces; the third and largest segment, which occupies a lower position than either of the others, descends spirally upon the crescentic margins of the other two, wedging and screwing them more and more tightly into each other. The spiral movement is occasioned by the direction of the sinuses of Valsalva, which curve towards each other and direct the blood in spiral waves upon the mesial line of each segment.

The *muscular fibres* of the heart are peculiar in presenting an intermediate form between the striped and unstriped varieties of muscular tissue; the fibres are smaller, and their striation is less strongly marked and less regular than those of ordinary striated muscle. This arrangement explains to some extent the uniformity and continuity of the cardiac movements. There is no trace of sarcolemma, and according to Eberth† the fibres are composed of broad quadrangular cells that are often forked at their extremities or give off lateral prolongations which are firmly adherent to each other. In a chemical point of view the muscular tissue of the heart is characterized by containing a larger amount of water than other muscles (79, instead of 76 per cent.); a considerable quantity of a peculiar kind of sugar, inosite, a very small proportion of kreatin, and a large amount of kreatinin.‡ The *nerves* of the heart are partly derived from the cerebro-spinal system, and partly from the sympathetic system. The two sets of fibres communicate in the cardiac plexus. The *cardiac plexus* receives branches, varying from one to three or more, from the trunk of the vagus on each side; a branch from the external laryngeal branch of the superior laryngeal, and one from the inferior laryngeal nerve of each side, and a branch from each of the cervical and the first dorsal ganglia of the sympathetic, though these vary greatly in size, and one is sometimes apparently wanting on one side.§ In addition, a few fibres are probably derived from the hypoglossal. Minute ganglia and ganglionic cells are distributed in the substance of the muscles, and lie also in the auriculo-ventricular and interventricular furrows. Some of

Fig. 118.

disparity in the size of the Auricles and Ventricles is considerable; Laennec, Cruveilhier, Gordon, Bouillaud, Meckel, and Portal that it is trifling; Lower, Sabatier, Weiss, Andral, and more recently Pettigrew, that there is no difference whatever.

* See Pettigrew, "Transact. of the Roy. Soc. of Edinb.," vol. xxii. 1864, p. 761; Gussenbauer, "Ueber die Muskelatur der Atriovent. Klappen des Menschenherzens, Wiener Sitzber." Band lvii. 1872.

† Virchow's "Archiv," Band xxxvii. Heft 1, p. 100. See also Schweigger-Seidel, Stricker's "Histology," New Syd. Soc. Trans. vol. i. p. 248.

‡ Ranke, "Grundzüge d. Physiolog.," 1868, p. 307.

§ See Heule, "Anatomie, Nerveulehre, p. 572.

the ganglionic cells resemble those of the sympathetic in giving off from one and the same pole a straight and a spiral fibre; others are bipolar; and others again form bi-celled ganglia, resembling two pears applied to each other by their broad ends, the stalks representing the nerves they give off. These have no spiral fibre. The precise mode of termination of the nerve fibres has not been made out, but they probably lose their double contours, and continuing their course as pale fibres form loops and anastomoses around the muscle cells.* It will be observed that in consequence of the absence of a sarcolemma the ultimate nervous plexus is in immediate contact with the contractile substance. The cavities of the Heart are lined by the 'endocardium' in which all the layers of a vascular wall are represented—viz., a single layer of endothelial cells, a stratum of fine elastic fibres, and a layer of connective tissue in which are distributed many unstriated muscle-fibre cells, for the most part arranged longitudinally. A rich plexus of nerves has been observed in it. According to Eberth and Belajeff,† the endocardium, especially in the ventricles, presents a mesh-work of fine *lymphatics*, the walls of which in some parts consist only of a single layer of intimately-adhering cells. No lymphatics are traceable on the chordæ tendineæ, and very few upon the auriculo-ventricular and semilunar valves. We shall now examine what agency in the Human Circulation may be attributed to the Heart, the Arteries, and the Veins respectively; and what other forces may be fairly presumed to operate in the Capillary circulation.‡

2. *Action of the Heart.*

215. The Heart is endowed in an eminent degree with the property of *Irritability*, by which is meant the capability of being easily excited to movements of contraction alternating with relaxation. Thus, after the Heart has been removed from the body and has ceased to contract, a slight irritation will cause it to execute, not one movement only, but a series of alternate contractions and dilatations, gradually diminishing in vigour until they cease. The contraction begins in the part irritated, and then extends to the rest. It appears, however, from Sir James Paget's experiments,§ that it is necessary for the propagation of this irritation, that the parts should be connected by muscular tissue which probably contains nerve fibres and of which a very narrow isthmus will suffice; the propagation will not take place if the connecting isthmus be composed of a portion of the auriculo-ventricular ring, which has been supposed by some to be peculiarly efficacious in this conduction.‖ Like the contractility of other muscles, that of the Heart can only be continuously sustained by a supply of arterial blood to its own tissue. This is shown not only by the serious effects produced by disease of the coronary arteries, but also by the experiments of Erichsen¶ and Schiff;** the former of whom found that ligature of the coronary arteries rapidly produced cessation of the movements of the heart, especially if the cardiac veins were also opened; whilst the

† Virchow's "Archiv," 1866, Band xxxvii. p. 55.

‡ Many of the phenomena of the circulation can be conveniently studied, and practice in the use of recording instruments, manometer, sphygmograph, kymographion, &c., obtained by means of an india-rubber model of the circulatory system constructed by Dr. Rutherford, and described in the Journal of "Anatomy and Physiology," vol. vi. p. 249.

§ "Brit. and For. Med. Review," vol. xxi. p. 551. See also Englemann, "Archiv f. d. gesammte Physiologie," Band xi. 465.

‖ Quinine in moderate doses appears to have a remarkable power of exalting the irritability of the heart, though in very large doses it depresses it. See Schtschepotjew, Pflüger's "Archiv," 1879, Band xix. p. 53.

¶ "Lond. Med. Gaz.," 1842, vol. ii. p. 561. ** "Arch. f. Phys. Heilk.," tom. ix.

latter obtained a local paralysis of either ventricle, according as the artery distributed to the one or the other was tied.* The contractility of the Heart is much less speedily lost in cold-blooded animals than in warm-blooded; the heart of a Frog, for instance, will continue to pulsate for as many as twelve hours after its removal from the body, particularly if kept in an atmosphere of oxygen, though it ceases in a few minutes if immersed in Carbonic acid gas.† It has further been shown by Mr. Tod, that the irritability of the heart is of great duration after death in very young animals; which, as was long since demonstrated by Dr. Edwards, agree with the cold-blooded Vertebrata in their power of sustaining life for a lengthened period without oxygen. That the heart in dilating exerts a distinctly marked suction power is shown by the negative pressure indicated by a manometer introduced into the auricles or ventricles. This negative or minus pressure in the auricles has long been known, but more recently it has been accurately measured.‡ Experiments show that whilst during systole the pressure in the left ventricle is at its maximum, and is the same as that in the aorta, amounting (in three dogs) to from 114 to 142 mm.; the minimum pressure during diastole was – 52 mm. Hg. In the right ventricle the maximum pressure was + 62 mm. Hg, and the minimum pressure was – 17·2 mm. Hg. In the right auricle its maximum pressure was 20 mm. Hg, and the minimum pressure – 11·2. That these minus quantities do not depend on inspiration is rendered evident by the fact that a negative pressure of – 23·5 mm. Hg was still observed after the thorax had been opened, and artificial respiration maintained.§ It is uncertain whether the suction power of the cardiac cavities is due to active muscular elongation, or to the elasticity of the walls of the thick masses of muscle striving to resume their hollow form after contraction.

216. The most reasonable explanation of the cause of the contractions of the heart is that which attributes them to the continuous excitation that the blood flowing through the cavities exerts on the cardiac excito-motor ganglia. This meeting with continuous resistances in the cardiac inhibitory ganglia—only periodically, that is to say, after overcoming such opposition—acts on the muscular tissue. Bowditch‖ has shown that the apex of the heart, when separated from the rest of the organ by a ligature or compression, remains absolutely at rest; or if, as occasionally occurs, it begins to beat again, it is due to the restoration of an imperfectly destroyed connection between the apex and the motor apparatus at the base of the heart. As already stated, Schweigger-Seidel has observed a rich plexus of nerve fibres in this membrane, whilst its sensitiveness to mechanical irritation was incidentally shown by an experiment of Bernard,¶ in which the contact of the bulb of a thermometer with the interior of the ventricles immediately increased the number of pulsations. Schiff** and Budge†† have, moreover, shown that the action of both auricles and ventricles rapidly ceases if they are placed on blotting-paper; but that they may be called into action again, either by immersing them in blood, or by dropping a little blood into their cavities. And an ingenious experiment was made by Haller himself, showing that if arrangements are made, by which either the right or left side of the Heart remains filled with blood

* v. Bezold, however, found that ligature of the coronaries produced but little effect for a considerable period in rabbits. † Castell, Müller's "Archiv," 1854, p. 226.

whilst the other can discharge its contents and remains empty, that side which is stimulated by the presence of the blood continues to beat rhythmically long after the movement of the other had ceased. When the irritability of the heart is nearly exhausted, the usual *rhythm* is often a good deal disturbed, so that the contractions of the auricles and ventricles do not regularly alternate with each other; and one set frequently ceases before the other.

217. When the Heart is exposed in a living animal and its movements are attentively watched, they are seen to follow each other with great regularity. In an active and vigorous state of the circulation, however, they are so linked together, that it is not easy to distinguish them into periods; both Auricles contracting, and also dilating, simultaneously; and both Ventricles doing the same. The *systole* or contraction of the Ventricles corresponds with the projection of the blood into the arteries; whilst the *diastole* or dilatation of the Ventricles coincides with the collapse of the arteries. The contraction of the Auricles and Ventricles run into each other, that of the Auricle immediately preceding that of the Ventricle. The entire period that intervenes between one pulsation and another is nearly equally divided between the systole and diastole of the Ventricles, but the division is very unequal as regards the Auricles; about one-fifth of the whole being occupied in their contraction, and the remainder being taken-up by their dilatation.* The following tabular view will perhaps make the relations of the several parts of this series more intelligible:—

Auricles.		Ventricles.	
$\frac{4}{5}$	Dilatation.	Contraction.	$\frac{2}{5}$
	Continued Dilatation.	First stage of Dilatation.	$\frac{2}{5}$
$\frac{1}{5}$	Contraction.	Second stage of Dilatation.	

In some very careful experiments, Donders† ascertained that in different persons in whom, when at rest, the pulse varied from 74 to 94 per minute, the duration of the systole of the ventricles—*i.e.*, from the commencement of the first to the commencement of the second sound—varied from 0·327 to 0·301 of a second, and that it constituted from 40·6 to 45·6 per cent. of the time occupied by an entire cardiac revolution. In a man whose pulse was only 32 per minute, the duration of the ventricular action was still 0·307 to 0·325 of a second, though its proportion to the whole revolution had fallen to about 18 per cent. From whence it appears that the duration of the activity of the Ventricles, determined by the ganglia of the heart itself, is independent of the duration of the entire cardiac revolution, which is regulated by the Pneumogastrics.‡ Landois,§ who has paid much attention to the subject, finds the

† "Nederlandsch Archief voor Genees- en Natuur-kunde," 1866, p. 139, of which paper a full translation is to be found in the "Dub. Quart. Journ.," vol. xlv. p. 225. See also some estimates by Landois, Henle and Meissner's "Bericht," 1866, p. 411. By some (Brücke, "Vorlesungen, a. d. Physiologie," 1874, p. 180) it has been supposed that the injection of the coronary arteries is the cause of the systole, their distension taking place during the diastole of the ventricle in consequence of the mouths of those vessels being covered during the systole by the semilunar valves; but careful examination has shown that the mouths of the coronary are, in a very large number of cases, above the level of the semilunar valves, and vivisection has shown that the coronary arteries when divided yield a jet synchronously with the systole. ‡ See Sibson, "Medical Anatomy," 1869, and the instructive papers by Dr. Halford, now Prof. of Physiology at the Univ. of Melbourne, "On the Times and Manner of the Closure of the Auriculo-Ventricular Valves," and "On the Movements and Sounds of the Heart," Lond., 1861; also Pettigrew's Lectures on the 'Physiology of the Circulation,' "Edinb. Med. Journ.," 1873.

§ Landois, "Physiologie," 1879, p. 94.

duration of the period *a b*, which includes the *pause and the systole of the auricles* (*a b*, Fig. 122), liable to considerable variation, and to be dependent on the number of the heart's beats in the minute, for of course the more quickly the heart beats the slower is the pause, and *vice versâ*. Even when the heart is beating slowly it is often impossible to distinguish between the horizontal line of the pause and the rise corresponding to the auricular systole. In one case, where the heart was beating 55 times in the minute, the pause lasted 0·4 second, and the auricular systole 0·177 second. In Fig. A, the pause + auricular systole (with a pulse of 74 per minute) lasted 0·5 second. In B the period *a b* (= 19–20 vibrations) lasted 0·32 second. The *Ventricular systole*, represented by the line *b*—*e*, persists from the beginning of the first to the beginning of the second sound. It is more constant than the preceding, but is shorter when the heart's action is rapid, longer when this is slow. In B it lasted 0·29 second. In a case when the pulse was 55 per minute it lasted 0·34, but with a very rapid pulse it may last only 0·199 second. It does not vary much in cases of great dilatation and hypertrophy of the ventricle. The *period* which elapses between *d* and *e*—that is to say, *between the complete closure of the aortic semilunar and of the pulmonary semilunar valves*—varies in proportion as the pressure in the aorta exceeds that in the pulmonary artery, and may therefore vary from an almost imperceptible period to 0·05 or 0·1 second. Lastly, the period in which the ventricles relax after closure of the

Fig. 119.

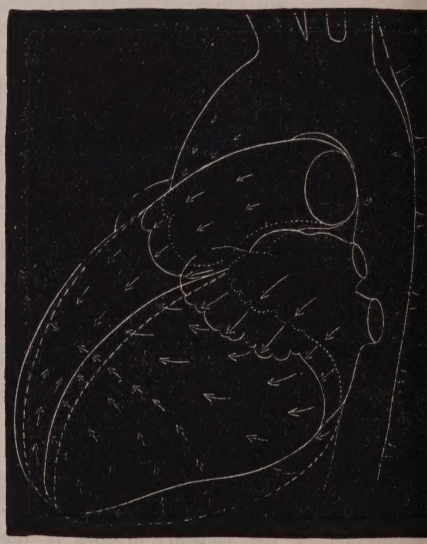
Fig. 120.



Profile view of the movement of the heart in systole and diastole.

valves represented by the line *e* to *f*, may on the average be estimated at 0·1 second. The extent and direction of the movements of the several parts of the heart in systole and diastole are well represented in Figs. 119, 120.*

* The outlines of the cavities of the heart, and the great vessels, are here indicated, at the end of the *systole* of the heart, by continuous lines—at the end of the *diastole* by interrupted or dotted lines. (The drawing and descriptions are taken from Dr. Sibson's admirable treatise on "Medical Anatomy," 1869, Col. 73. The dotted lines are less accurate than the interrupted lines.) The systolic movements are everywhere shown by arrows, the extent of

An entire cardiac revolution may be described in the following terms, commencing with the systole or contraction:—The Auricles and Ventricles are both filled with blood, which has flowed into them from the veins. The Auriculo-ventricular valves are open, and the arterial valves (both aortic and pulmonary) are perfectly closed. Commencing at the entrance of the great veins, a sudden contraction of the Auricles now takes place, which extends without appreciable pause in a peristaltic manner over the ventricles. By the contraction of the Auricles a portion of their contained blood is discharged into the Ventricles, completing the distension of these cavities, and effecting the closure of the Auriculo-ventricular valves which float up into contact. The Ventricles instantly contract tightly, closing the Auriculo-ventricular valves and forcing open the arterial valves, through which the blood is propelled into the arteries. The great arteries, now distended with blood, recoil on their contents and close the semilunar valves. As soon as the contraction of the Ventricles is completed, a sudden movement of relaxation takes place similar to that of an elastic bag when released from pressure, and this is followed by a brief interval of complete rest; during which both Auricles and Ventricles are rapidly filling with blood; contraction then again recurs. During the systole the heart becomes more globular, or, perhaps strictly speaking, more conical in form. The chief movement observable in the Auricles is the sudden retraction of the appendices, which almost instantly become refilled with blood as the ventricles contract. The contraction of the two ventricles seems to take place simultaneously towards a centre or point of rest, which in the right ventricle, where the action is most easily observed, is situated about the middle of its length, near the septum and opposite the attachment of the anterior papillary muscle (Sibson). The base of the heart descends rather more than the apex ascends. There is a slight twisting movement of the whole heart during the systole, both on its longitudinal and on its transverse axis. By its rotation on its transverse axis the apex of the heart is tilted forwards; by its rotation on the long axis the left ventricle, which during the diastole looks backward, is turned forwards. The combination of the two *movements* gives to the apex a twisting movement from left to right and forwards. The apex beat is felt between the 5th and 6th ribs, and is caused by a part just above the apex. In the act of contraction the heart may be felt to become hard. During the diastole the heart undergoes a change in form, the converse of that which has been above described. The *impulse* is felt over every part of the Ventricles during their contraction, but most forcibly over their centre. It is synchronous with the first sound of the heart, with the opening of the auriculo-ventricular valves, the dilatation of the aorta, the arterial pulse, and the jet of blood that occurs when an opening has been made through the walls of the ventricle. Senac and Hunter* attributed the impulse to the effort of the arch of the aorta to straighten itself when blood is forced into it by the systole of the heart, the aorta being the fixed point against the back, and the heart in some degree loose or pendulous, the influence

the movements being marked by the length of the arrows. As it is more difficult to watch and measure the movements of the heart from the side than from the front, the side view (Fig. 120) is not so accurate as the front view (Fig. 119). Brücke ("Vorlesungen," 1874, p. 172), whose experiments were made by implanting needles into the hearts of rabbits, and watching the reversed motions of the heads, maintains that all parts of the ventricles move downwards in systole with the exception of the apex, the amount of movement increasing from below upwards. Halford (op. cit.) believes the apex of the heart is drawn up towards the base, but nevertheless undergoes less change of position than any other part, its upward movement being neutralized by the descent of the whole heart occasioned by the elastic recoil of the great vessels springing from the base.

* "Hunter's Works," by Palmer, vol. iii. p. 185.

of its own action is thrown upon itself, and it is tilted forwards against the inside of the chest. Colin* and others have shown, however, that this cannot be the only cause, since the impulse is felt when all the vessels are compressed or tied, and it seems probable that it is chiefly, or in part, due to the shortening, tilting, and pressure of the heart against the parietes of the chest, which occurs in systole.

218. The course of the circulating fluid through the Heart, and the action of its different valves, will now be briefly described.—The Venous blood, which is returned by the ascending and descending Vena Cava, enters the *right* Auricle during its diastole, on the contraction of which it is propelled through the tricuspid valves into the Ventricle, which thus becomes completely distended. The reflux of blood into the veins during the auricular systole, is impeded by the contraction of their own walls, and is limited on the right side by the valves placed at the junction of the jugular and subclavian veins; but these valves are so formed as not to close accurately, especially when the tubes are distended; so that a small amount of reflux usually takes place, and this is much increased when there is any obstruction to the pulmonary circulation. Whilst the *right* Ventricle is contracting upon the blood that has entered it, the *carneæ columnæ*, which contract simultaneously with its proper walls, put the *chordæ tendineæ* upon the stretch, preventing the flaps of the Tricuspid valve from being driven back into the auricular cavity. The blood is now expelled by the ventricular systole into the Pulmonary artery, which it distends, passing freely through its Semilunar valves; but as soon as the *vis a tergo* ceases, and reflux might take place by the elastic recoil of the arterial walls, the valves are filled out by the backward tendency of the blood, and completely check the return of any portion of it into the ventricle. The blood, after having circulated through the lungs, returns as Arterial blood, by the Pulmonary veins, to the *left* Auricle; whence it passes through the Mitral valve into the *left* Ventricle, and thence into the Aorta through its Semilunar valves in the same manner with that on the other side, as just described.† There is a well-known anatomical difference between the auriculo-ventricular valves on the two sides, which has given rise to the diversity of name; and this seems, from the researches of Mr. King,‡ to be connected with an important functional difference. The Mitral valve closes much more perfectly than the Tricuspid; and the latter is so constructed as to allow of considerable reflux, when the cavities are greatly distended. According to Dr. Flint,§ an equally well-marked difference in sufficiency also exists between the arterial semilunar valves on the two sides, the closure of the pulmonary being much less perfect than the aortic. Many occasional causes tend to produce an accumulation of blood in the venous system, and in the right side of the Heart; thus, any obstruction to the pulmonary circulation, cold, compression of the venous system by muscular action, &c., are known to favour such a condition. This is a state of peculiar danger, from a liability which over-distension of the Ventricular cavity has to produce a state of muscular paralysis; and in the structure of the Heart itself there seems, as just stated, to be a provision against it. For, when the ventricle is thus distended, the Tricuspid valves do not close properly; and a reflux of blood is permitted, not only into the Auricle, but also (through the imperfect closure of their valves under the same circumstances) into the large

‡ "Guy's Hospital Reports," vol. ii. § "Physiology," 1866, p. 203.

veins. This is proved by the fact, several times observed by Dr. J. Reid in his experiments upon Asphyxia, &c., that when the action of the right ventricle had ceased from over-distension, he could frequently re-excite it, not merely by puncturing its walls, but by making an opening in the jugular vein.* This fact evidently affords an indication of great importance in the treatment of Asphyxia; and it explains the reflux of blood, or *venous pulse*, which is frequently observed in cases of pulmonary disease, and which, according to Mr. King, always exists even in health, though in a less striking degree.†

The movements of the blood through the heart and large vessels contained in the chest is to some extent influenced by the respiratory acts. Whilst a full inspiration is taken, not only does air enter through the trachea, but blood enters through the great veins to fill the vacuum which the descent of the diaphragm tends to produce. Were it not for the valves and for the greater strength of their coats it would also enter by the arteries. The auricles become distended, and do not at first deliver their blood freely to the ventricles, and the pulse is therefore feeble and small, though after a short time it becomes stronger and fuller. In extreme expiration, on the contrary, the chest cavity is diminished in size; the lungs, and with them the heart, are compressed, hence little blood enters the heart in diastole, and little is driven out; therefore the systole and the pulse at the wrist are feeble. The alternate expansion and contraction of the chest cavity which occurs in normal respiration is most favourable to the circulation, for there is then a certain tendency to dilatation of the cardiac cavities during diastole, and yet there is no interference with the discharge of the blood during systole. If, instead of allowing the glottis to remain open after a deep inspiration it is closed, and a strong expiratory effort be made (Valsalva's experiment), the cavities of the heart may be so compressed that the current of blood is arrested. Blood enters the heart with difficulty, as is shown by the swelling of the veins of the neck, and this little passes rapidly through the expanded lungs into the left Ventricle, which quickly discharges it. The lungs and heart then are both empty, and the cardiac sounds and pulse may almost or quite cease. If, on the contrary, a full expiration be made, and the glottis being closed, a strong inspiratory effort be made, the cavities of the right heart become distended; for the elastic traction of the lungs is exerted and the rarefaction of the air in the chest promotes the entrance of blood through the great veins, the lungs become filled with blood, whilst but little blood enters the left heart, and hence again the pulse becomes small or imperceptible. The pulmonary or intra-thoracic circulation is aided by the elastic traction exerted by the lungs, for the blood in the capillaries of the lungs moves under the pressure of the air in the lungs; whilst that in the pulmonary veins moves under a lower pressure, because the elastic traction of the lungs, by tending to dilate the left auricle, must operate favourably to the discharge of the blood from the capillaries into the left auricle. The elastic traction of the lungs upon the right ventricle, and consequently upon the movement of the blood through the pulmonary artery, is exerted to a less extent on account of its strength.

* "Physiol., Anatom., and Pathol. Researches," chap. iii.

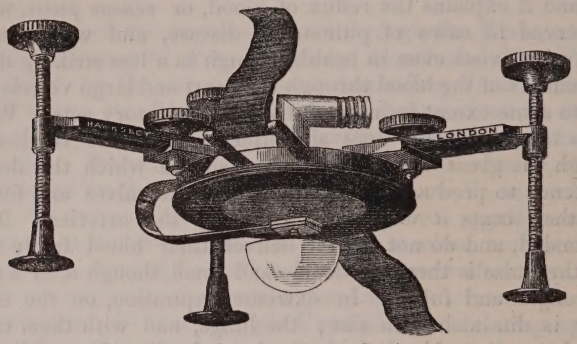
† Dr. Herbert Davies ("Proceed. Roy. Soc.," No. 118, 1870, and pamphlet) maintains that the four chief orifices of the heart are circular in form and constant in area during the entire periods of systole and diastole, and that they bear an exact mathematical relationship to each other, expressed by the formula—

$$\frac{\text{Area of tricuspid}}{\text{Area of mitral}} = \frac{\text{Area of pulmonic}}{\text{Area of aortic}}$$

but his conclusions have been controverted on mathematical grounds by Mr. Trotter, "Journ. of Anat.," 1870, p. 298.

The experiments of MM. Chauveau and Marey,* with a peculiar form of Cardiograph, represented in Figs. 121, 123, in which levers of extreme lightness register the undulations of the air contained in elastic sacs applied to the surface of the Heart and Thorax, show clearly the sequence and duration of

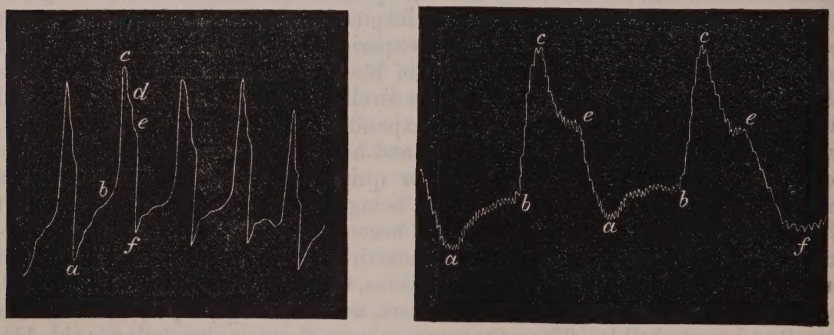
FIG. 121.



Marey's drum for registering Cardiac impulses.

the movements of the Auricles and Ventricles, and the coincidence of the *impulse* with the contraction of the Ventricles (Figs. 122, 124). The Cardiograph, as modified by Sanderson, consists of a hollow disc of brass, the front

A FIG. 122. B



Cardiac Impulse Tracings.

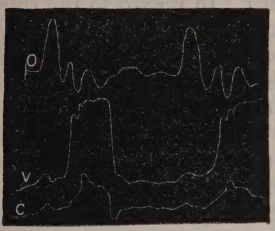
B. Normal curve of Man registered on a vibrating tuning-fork plate. Each undulation corresponds to 0·01613 of a second. In both tracings *a*, *b*, represents the systole of the auricle; *b*, *c*, the systole of the ventricles; *d*, the closure of the aortic valves; *e*, closure of the pulmonary valves; *e*—*f*, diastole of the ventricle.

of which is closed by a thin india-rubber membrane called a tympanum. To the brass back a flat steel spring is screwed, which is bent twice at right angles in such a way that its extremity is opposite the centre of the tympanum. The extremity is perforated by a steel screw, the point of which rests on the membrane, whilst its head is surmounted by an ivory knob. The tympanum is provided with three adjusting screws, by which when in use it rests on the wall of the chest with its face parallel to the surface, and can be approximated or withdrawn at will. The cavity of the disc communicates by a vulcanized india-rubber tube with a second tympanum represented by *b* in

* "Annal. des Scien. Nat.," 4th sér., Zool., tom. xvii. p. 374; and "Mém. de la Soc. de Biol.," sér. iii. tom. iii. pt. ii. 1862, p. 1. For other Cardiographic tracings and accounts of the instruments employed, see A. H. Garrod in "Journ. of Anat. and Phys.," Nov. 1870, and Rutherford's Lectures in "Lancet," 1871–2.

Fig. 123, in such a way that the two tympana and the tube enclose an air-tight cavity. The movement of the second tympanum is magnified and inscribed on a registering cylinder by a lever. The causes of the impulse according to Sibson are, first—the rigidity of the muscular walls during contraction; secondly, a lever movement forward, due to the thickening of the muscle, which occurs during contraction, being resisted by the fibrous bed of the pericardium on which the heart rests; and, lastly, the outward pressure of the blood in the ventricles on the walls by which it is expelled, and through those walls on the ribs and intercostal spaces.

Fig. 124.



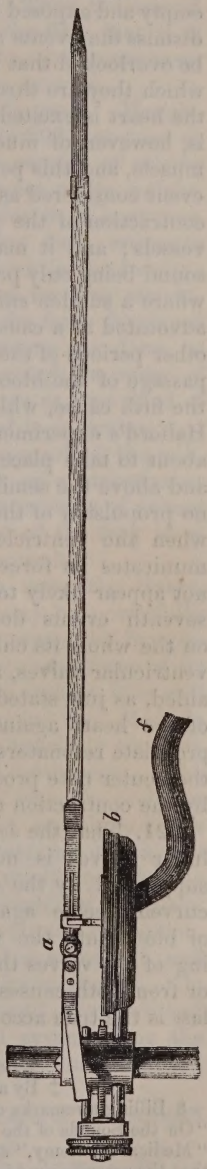
Tracing obtained by the Cardiograph of MM. Chauveau and Marey.

In this tracing *o* represents the short and abrupt contraction of the Auricles which immediately precedes the more energetic and protracted contraction of the Ventricles, represented by the line *v*. The line *c* shows the impulse of the Heart to be coincident with the Ventricular contraction.

219. When the ear is applied over the cardiac region, during the natural movements of the Heart, two successive *sounds* are heard, each pair of which corresponds with one pulsation; there is also an *interval of silence* between each recurrence, and the sound that immediately follows this interval is known as the *first* sound, the other as the *second*.—The *first* sound is dull and prolonged, and is heard all over the left ventricle with equal intensity; it is evidently synchronous with the impulse of the Heart against the parietes of the chest, and also with the pulse, as felt near the heart; it must, therefore, be produced during the Ventricular Systole.—The *second* sound, which is short and sharp,* follows so immediately upon the conclusion of the first, that it cannot take place during the auricular systole as some have supposed, but must be assigned to the first stage of the ventricular diastole, when the auricles also are dilating.

220. The causes of the sounds, and more especially of the *first*, have been the subjects of much discussion. A number of very distinct actions are taking place during the period of the production of the latter; and each of these has been separately fixed on as competent to produce it. Thus, we have (1) the impulse of the heart against the parietes of the chest; (2) the contraction of the muscular walls of the ventricles; (3) the rush of blood through the narrowed orifices of the aorta and pulmonary artery; (4) the general molecular collision of the particles of the blood amongst each other, and their friction against the walls of the ventricles; (5) the sudden collision of the stream of blood issuing from the ventricles with the column of blood at rest on the semilunar valves of the aorta and pulmonary artery; (6) the friction of the heart against the pericardium; (7) the vibration of the walls of the chest from the sudden rigidity and pressure of the

Fig. 123.



Marey's apparatus for registering Cardiac impulses.

* The difference between these two sounds is well expressed (as Dr. C. J. B. Williams has remarked) by articulating the syllables lubb, dŭp.

heart; and (8) the sudden tension of the valves of the auriculo-ventricular orifices. In regard to the first event, it may be remarked that excellent observers, as Ludwig and Dogiel,* Sibson and Broadbent, maintain that though much reduced in intensity the first sound is still audible during the contractions of an empty and exposed heart and after removal of the chest walls, which enables us to dismiss the events numbered above, 1, 4, and 5, as efficient causes. It must not be overlooked that the *susurrus* of ordinary muscles is due to the vibration into which they are thrown during contraction, whilst Marey has shown that when the heart is excited to contract the shortening of the fibres is a single act. It is, however, of much longer duration than the contraction of ordinary striated muscle, and this perhaps enables it to be perceived.† In regard to the third event considered as a cause, it has been well remarked,‡ that there is no abrupt contraction of the passages through which the blood flows from ventricles to vessels; and it may be added, that there would be no sound if there were; sound being only produced at that point in a vessel conveying a stream of fluid, where a sudden *enlargement* occurs. In regard to the fourth event, strongly advocated as a cause by Sibson and Broadbent, it may be argued that during other periods of the heart's rhythm, such collision produces no sound, as in the passage of the blood from the auricles to the ventricles; and in reference to the fifth cause, which has been advanced by Dr. Leared, it appears from Dr. Halford's experiments, that at the moment when the systole of the ventricle is about to take place, the active and passive columns of blood, or those below and above the semilunar valves, are not separated by any space; that there is no propulsion of the blood from a distance against the passive column, but that when the ventricles contract, the fluid pushes open the valves and communicates its force to the column in the vessels, a circumstance which does not appear likely to be accompanied by much, if any sound. The sixth and seventh events doubtless aid in the production of the first sound, but on the whole its chief factors appear to be the sudden tension of the auriculo-ventricular valves, and the contraction of the muscular walls of the ventricle, aided, as just stated, by the vibration of the walls of the chest, and the friction of the heart against them.§ Wintrich,‖ indeed, states that by the aid of appropriate resonators he has been able in the first sound to discriminate between the acuter note produced by the valvular tension from the deeper sound caused by the contraction of the muscle.¶

221. That the *second* sound is produced in the act of closure of the semilunar valves is now almost universally admitted, since it is altogether suppressed by the simple act of hooking back one of these valves with a curved needle against the side of the artery so as to permit a reflux of blood into the ventricle. Whether it proceeds from the sudden tightening of the valves themselves, or from the recoil of the blood against them, or from both causes combined, has not been clearly determined; probably the last is the true account of it.—When the first sound is altered by disease of the

† See Marchand, Pflüger's "Archiv," Band xv. p. 511.

‡ By a writer in the "Med.-Chir. Rev.," April, 1860, p. 354.

§ Billing's remarks upon this subject in his "Principles of Medicine," Halford's pamphlet "On the Sounds of the Heart," and the observations of Sibson and Broadbent in Sibson's "Medical Anatomy," are deserving of careful perusal. For some exceptional statements, as that the second sound is due to a contraction of the auricles, see Paton 'On Sounds of Heart,' in "Dub. Quart. Journ.," vol. xcix. p. 83, *et seq.* The various treatises on practical medicine and auscultation may also be referred to. Dr. Dunglison, "Human Physiology," vol. i. 1856, p. 397, has tabulated the opinions of a large number of authors. They exhibit an extraordinary amount of discordance upon a matter of pure observation.

‖ Hofmann and Schwalbe's "Jahresbericht," Band ii. 1873, p. 537.

¶ See also Arnold, "N. York Med. Journ.," April, 1878.

semilunar valves, occasioning obstruction to the exit of blood, the second sound also is affected in its character; and if the disease be of such a kind as to prevent these valves from effectually closing, a reflux of blood takes place into the ventricle at the time of its diastole, causing a rushing sound that is analogous to the ordinary first sound, or to some of its modifications. Thus, the second sound may come to acquire so completely the character of the first, that it is difficult to distinguish the two in any other way, than by the synchronousness of the first with the heart's stroke and with the pulse in the arteries.

The mechanical force put forth by the heart is wonderfully great. Haughton* estimates the total daily work of both Ventricles at 124·208 foot-tons, or admitting the weight of the heart to be nine ounces, it is capable of raising 20·576 pounds one foot in height per minute for every ounce of its weight, which considerably exceeds the work done by the muscles in a boat-race. Dr. Andrew Buchanan,† proceeding upon somewhat different data, estimates the force exerted by the heart per diem to be 42·3 foot-tons in the twenty-four hours. Helmholtz‡ calculates that the heart can raise its own weight, through 20,250 ft. in one hour, and Ranke§ estimates that the force developed by the left Ventricle alone amounts to 64,800 kilogrammeters per diem, or that it would be sufficient to raise 142,560 lbs. avoird. through the space of 39·37 inches; the force of the right Ventricle he estimates at one-third of the above. Whichever estimate is taken the power exerted is enormous, and greatly in excess of any effort of the muscles under the control of the will. Each systole of the heart is accomplished by a single shock or contraction or *sécousse*, and not by a series of shocks, as in the case of the muscles of animal life. The duration of the shock in the case of the heart of the frog is as much as fifteen times longer than that of ordinary striated muscle.

222. In regard to the influence of the Nervous system upon the Heart, there is abundant evidence to show that its movements may be powerfully affected by causes acting either upon the Cerebro-spinal or upon the Sympathetic system; and whilst, upon the one hand, the energy and force of its contractions may be augmented by stimuli applied to these centres, it is well ascertained that the Pneumogastric nerves, originating in the Medulla oblongata, are the means of conveying an influence of a precisely contrary nature, serving to inhibit, restrain, or regulate the Cardiac movements. The fact that the Heart will continue to beat after its removal from the body, or after the *gradual* removal of the whole Cerebro-spinal axis, especially if the flow of blood through the Lungs be kept up by artificial respiration,‖ as well as the existence of anencephalic monsters which possess a regularly-pulsating heart, clearly show that this organ is not exclusively or *essentially dependent* upon the central nervous system for the continuance of its rhythmical action. Its movements under these circumstances must be regarded as automatic, and governed by the Cardio-motor ganglia distributed through its substance. On the other hand, the well-known effects of mental emotions and of sudden and severe injuries of either the Sympathetic or Cerebro-spinal system upon the Heart's action, prove with equal certainty that its action may be influenced through nervous fibres in connection with those centres.

223. *Excito- or Cardio-motor System of the Heart.*—Careful dissections¶

‖ See the Experiments of Dr. Wilson Philip, "Experimental Inquiry," &c., p. 56.

¶ By Remak, Müller's "Archiv," 1844, p. 463; Bidder, "Archiv f. Anat. und Physiol.," 1868, p. 1; Lee, "Philosophical Transactions," 1869; and Beale, "Quart. Journ. of Microscop. Sci.," April, 1869. See also Friedländer, "Unters. a. d. Physiol. Labor. in Wurzburg,"

have shown that whilst small ganglia and nerves are very generally distributed through the substance of the heart in the Frog, except near the apex of the ventricle, special collections of ganglia are found in two places: the first, known as the *ganglion of Remak*, is placed in the sinus venosus, near the opening of the inferior vena cava; the second, termed the *ganglion of Bidder*, is imbedded in the auriculo-ventricular septum. The functions of these ganglia may be demonstrated by experiment. If the heart of a frog after excision be kept thoroughly moist with blood or serum, it will continue to beat for many hours. The cause of the movement must necessarily therefore be in the heart itself, and may be in part attributed to a natural tendency of the cardiac muscular tissue to contract rhythmically and in part to the orderly discharge of impulses from nerve ganglia scattered through its substance. The stimulus to the ganglia of the excised heart is probably the contact of the blood or serum with the nerves of the endocardium, and the action of the heart is then said to be "automatic;" but when the heart is in position and acting naturally, the ganglia may be excited by stimuli applied to other parts of the body, and the heart is then said to be "reflectorially" excited. An experiment devised by Stannius* throws much light on the position and function of the cardiac ganglia. The two venæ cavæ (S.V.C., I.V.C., Fig 125) in this animal unite before entering the right auricle to form a dilatation called the sinus venosus (S.V.). The cavities of the right and left auricles, R.A., L.A., communicate with each other in consequence of the imperfection of the septum, but discharge their blood through separate orifices into the ventricle V., from which it is transmitted by a partially divided aorta (not shown in the Figure) to the lungs and brain, the lungs receiving chiefly the impure blood which has entered the ventricle from the right auricle, the head that which has been aërated from the left. In the wall of the sinus venosus is a ganglionic nerve mass termed the ganglion of Remak, and near the junction of the inter-auricular with the auriculo-ventricular furrow is a second one known under the name of Bidder's ganglion. Now, if a ligature be applied between the sinus venosus and the right auricle (at *a*) the heart suddenly ceases to beat, and remains in a state of relaxation or diastole, but the sinus itself continues to act. If the auricles or ventricle be directly stimulated, they immediately respond to the stimulus and execute a few movements. If a second ligature be applied between the auricles and ventricle, the auricles remain quiescent whilst the ventricle resumes its rhythmical action.

* "Zwei Reihen physiologische Versuche," 1851.

224. The explanation advanced by Rosenthal of these phenomena is, that both the above-mentioned ganglia are automatic centres, receiving their stimulus to action within the heart. Remak's ganglion is extraordinarily irritable, the slightest stimulus conveyed to it being sufficient to cause it to liberate an impulse which, as its efferent fibres are distributed to both the auricles and the ventricles, induces their contraction. If a ligature be applied at *a* these efferent fibres are compressed or divided, and the heart is stopped in diastole. Bidder's ganglion is an accessory automatic ganglion that is much less irritable, requiring, for example, such a stimulus as the increased rush of blood to the heart that occurs in violent exertion to stimulate it. When the heart is arrested by the application of the ligature at *a*, the ventricle recommences its rhythmical action on the application of a ligature at *b*, because this acts as a powerful stimulus to the ganglion, and the auricle does not beat because the ligature happens to be above it; but if the ligature happens to pass through its centre, then both auricles and ventricle may be set in action. Another explanation suggested by Bidder is that Remak's ganglion is the proper automatic ganglion of the heart, receiving its stimuli from the endocardium, whilst Bidder's ganglion is excited to act reflectorially, that is to say, from stimuli acting on nerves outside the heart, which stimuli, after the application of the ligature, it no longer receives; or yet again, it may be that a ligature around the auriculo-ventricular furrow may stimulate the fibres of the vagus passing to a third ganglionic centre situated near the ganglion of Bidder, and possessing an inhibitory function. As long as Remak's ganglion and Bidder's ganglion act together they are superior to the inhibitory ganglion, and the heart continues to beat; but if the power of the inhibitory ganglion be greater than either of the two motor ganglia alone, when the connection between these two is severed the heart will remain at rest. The cardio-motor system of nerves may be affected by *mechanical*, *chemical*, *electric*, and *thermic* stimuli. Bernard, for example, observed acceleration of the heart's beats when the bulb of a thermometer, introduced through the superior vena cava, touched the endocardium; and a similar effect was noticed (in Mammals at least, though the opposite occurred in cold-blooded animals*) by Ludwig when the blood-pressure was increased. Again, the presence of blood or serum in the chambers of the heart greatly prolongs its activity, partly by its mechanical excitation, but partly also by affording nutritive materials and a supply of oxygen. The importance of oxygen is well shown by an experiment made by Wündt,† who observed that the heart of a frog continued to beat for twelve hours in oxygen, whilst it ceased to move in ordinary air after three hours, in nitrogen and hydrogen after one hour, and in vacuo in half an hour. Certain gases, as chlorine, sulphurous acid, hydrogen sulphide, and certain poisons, as strychnia, opium, Calabar bean,‡ are capable of more or less rapidly arresting the movements of the excised heart when directly applied to it, by their chemical action on the cardio-motor system. Various salts, as those of sodium and rubidium (Grandeau and Bernard) when in large quantity, and those of the biliary acids (Röhrig) slow or arrest the heart's action; as do also certain acids, as acetic and citric acid (Bobrik), and phosphoric acid (Leyden and Monk).

The action of induction shocks on the heart has been studied by Bowditch,§ Marey,‖ and Hildebrand,¶ and presents several points of interest. In the

¶ Abstract in Hofmann and Schwalbe's "Jahresbericht," Band vi. p. 53.

first place, each systole of the heart resembles a single vibration or *sécousse* of an ordinary voluntary muscle, differing only in the remarkably long interval that elapses between two successive *sécousses;* and whereas induction shocks applied to striated muscle cause the vibrations rapidly to fuse together, the muscle passing into a state of strong permanent contraction, named tetanus; in the case of the heart, the application of moderately strong and moderately frequently repeated shocks does not induce tetanus, but only accelerates the rhythmical contraction, and it is remarkable that a weak and a strong electrical stimulus alike cause the ventricles to contract with their maximum vigour. The vigour of each contraction depends in great measure on the interval between it and the preceding one.

Another peculiarity of the muscular tissue of the heart is that its excitability is not the same at all periods of a cardiac revolution; for although a very strong stimulus or shock will always induce a contraction, a weak shock will only cause contraction during a certain period of a complete revolution, the heart at another period being incapable of responding, or presenting what may be termed a "refractory phase," the duration of which varies with the intensity of the stimulus and the state of the heart. With weak stimulation the refractory phase of the ventricle lasts throughout the period of systole, with stronger stimulation it lasts only during the first part of the systole, and with strong currents disappears altogether. Heat abridges, cold protracts the refractory phase. The refractory phase of the auricles lasts during the greater part of the diastole of the ventricle. Upon the whole there is a strong tendency on the part of the heart to work uniformly, so that an artificially induced systole is followed by a longer diastole, whilst such a systole is always more vigorous and its latent period less in proportion to the interval that has elapsed since the last spontaneous systole. When a succession of weak electrical stimuli are made to act on the heart, the great majority find it in the refractory phase, and hence the number of systoles is much less than that of the irritations; but if the electrical shocks are made to increase in intensity, the refractory period becomes shorter and shorter, and the tracing rising by successive increments, so as to present a series of steps or "staircase beats," till at last, when the stimuli are sufficiently strong, the heart passes into tetanus. The action of *continuous currents* of short duration resembles that of induction currents, weak continuous currents of short duration applied during the non-refractory stage simply accelerating the beats, whilst strong currents send the heart into a state of tetanus. The rapidity with which the wave of contraction is propagated varies from 10–30 mm. ($\frac{1}{2}$–$1\frac{1}{4}$ inch) in a second,* or, according to Marchand, even to 0·1 mm. per second,† and the latent period amounts to from 0·115—0·221 sec. in summer frogs, and from 0·177—0·308 sec. in winter frogs.

225. *Effects of Variations of Temperature upon the Heart's Action.*‡—From

* Eugelmann, Pflüger's "Archiv," Band xi. p. 465.

† Marchand, Pflüger's "Archiv," Band xv. 1877, p. 511.

‡ The effects of variations of temperature upon the heart have been studied by Pickford, Henle and Pfeuff., "Zeits.," 1851; Calliburcés, "Gaz. Hebdomad.," 1857, p. 468; Tigger, "Dissert.," 1853; Liebermeister, "Deutsch. Archiv f. Klin. Med.," Band i. p. 464; Schelske, "Ueber der Veränderungen der Erregbarkeit durch die Wärme," Heidelberg, 1860; Panum, see Abstract in Schmidt's "Jahrbücher," 1858; Cyon, Ludwig's "Arbeiten," 1868, p. 77; and Brunton, "St. Bartholomew's Hosp. Reports," vol. vii. 1871, p. 216; Wernicke, Preyer's "Sammlung," Jena, 1876; Cleland, "Journ. of Anat. and Physiol.," vol. xi. p. 754; Prof. Garrod, "Proceed. Roy. Soc.," 1870, p. 351, 1875, p. 142, who is supported by Mr. Thurston, Humphrey's "Journal of Anatomy," vol. x. 1876, p. 501, finds that the length of the systole of the heart, as indicated in the radial artery, is constant for any given pulse-rate, and varies as the cube-root of the rapidity.

numerous experiments, chiefly made on the frog, it appears that the heart only beats within certain limits of temperature, though these are not very well defined; in regard to the lower limit of temperature, the hearts of some animals cease to beat at 32° F., others not till exposed to a temperature of 25° F.; in regard to the higher limit of temperature the variation is still greater, some hearts being arrested at 86° F., and others not till 104°. In ascending *slowly* from the lower to the higher limits, the frequency of the heart's action steadily increases till it reaches a maximum, and then as the higher limit is approached it suddenly, but somewhat irregularly falls, as is represented in the adjoining cut (Fig. 126), where the abscissa may be considered as divided into degrees of temperature, whilst the ordinates would represent the relative frequency of the heart's action. Near the higher limit at which the heart's movements are arrested, the heart beats irregularly, so that the duration of the successive periods of diastole vary considerably, and just before stopping the contraction of the heart is no longer sudden and complete, but undulatory or peristaltic in character. In regard to the variation in the force of the beats of the heart which occurs with rise of temperature, Cyon has shown that the curve representing it attains its maximum very near the lower limits of temperature, and remains at the same height till a temperature of between 59° F. and 66° F. is reached, from which it progressively falls to zero. At the higher temperature little or no fluid is propelled from the heart, owing to the peristaltic character of its contractions. The conclusion that may be drawn from the above facts is, that there is a certain temperature at which the combined frequency and force of the heart's action produces its greatest effect in driving the blood through the vessels. For the frog this lies, according to Cyon, between 64° and 72° F. The phenomena in Cyon's experiments were somewhat different when the changes of temperature in the air surrounding the excised heart, and the serum flowing through it were *sudden*. Cyon found that if a heart that had been beating regularly at about 70° F. were suddenly cooled to 32° F., the force of the contractions underwent great diminution, the movements assuming a peristaltic character, and the heart becoming considerably dilated (heat diastole). After a time, however, it began to beat more strongly, and behaved as if it had been gradually cooled. If after being kept at 32° F. for some time it was suddenly exposed to air and serum at a temperature of 104°, the beats succeeded one another more and more rapidly till the whole organ passed into a state of tetanus (heat tetanus), lasting from 15–30 seconds. It then began to beat again, and passed through the same stages in the course of 1½–2 minutes that it presented in being gradually warmed. When a heart was suddenly heated, not from 32° F., but from about 55° to 104° F., the beats instead of becoming quicker became slower and fuller, and the traces resembled those of a heart in which the vagus is irritated. This state lasted for 1–2 minutes, and then the heart passed through the same stages that it would otherwise have presented if it had been gradually warmed. It thus appears that if the temperature be raised above that of "heat diastole" "heat-rigor" is produced, and the movements of the heart cannot again be restored by cooling it. The excitability

Curves showing force of the contraction of the heart with increase of temperature.

of the inhibitory nerve apparatus is abolished during the arrest of the heart's action from heat, for Cyon has shown that irritation of the sinus venosus, which invariably produces arrest of the heart's action in diastole under normal conditions, causes tetanus of the ventricle when applied to a heart that is in a state of arrest from heat. In *warm-blooded animals* the frequency of the heart's beats also increases with the temperature within certain limits (Panum, Brunton). In one instance, by means of registering apparatus, Dr. Brunton found that the heart of a rabbit, when the animal was exposed to a temperature of 105° F., beat 472 times in a minute. After reaching a maximum the beats become slower, and the heart finally stops. The increase is not the same for each degree of rise in the temperature; and the number of beats at the same temperature, and also the amount of quickening for each degree of rise of temperature, differs in different animals. The upper limit at which the heart stands still in rabbits is about 113° or 114° F. (Brunton); as the temperature to which the heart is exposed rises, and the pulse quickens, the inhibitory power of the vagus diminishes, but when the temperature had risen in Dr. Brunton's experiments to nearly its upper limit, the power of the vagus was again observed to be increased, and—contrary to expectation—to be strongly marked just before the heart ceased to beat. Schiff* observed that stimulation of the vagus caused acceleration instead of slowing of the heart's movements in rabbits that had been kept for some time at a temperature of 37°–38° C. (98°–100° F.). It is not improbable that the increased frequency of the heart's action in febrile conditions of the system is in part due to the stimulating effect upon the heart of the increased temperature of the blood caused by augmented tissue change.

226. *Nerves Retarding or Inhibiting the Action of the Heart.*—In the year 1846 the brothers Weber† observed the important fact which proved the starting point of numerous researches on the influence of the nervous system upon the heart, that irritation of the Vagus, or of its inferior cut surface in the neck, by means of an interrupted current of electricity caused the rhythmical movements of the heart to become slower, and if the current were sufficiently

Physiol. Heilk.," 8ter Jahr.; Moleschott, "Wien. Med. Wochens.," 25th May, 1861; and Lister, "Proceed. Roy. Soc.," vol. ix. p. 367, were led by their researches to consider the vagus as a motor nerve of extreme excitability, but which was easily exhausted. They maintained that with very feeble currents applied to it the heart's action is accelerated; but Pflüger, v. Bezold, Rutherford, Wündt, and many others have been unable to corroborate these statements. Later experiments have shown, however, that certain accelerator fibres do run in the trunk of the vagus; see Schiff's "Physiologie," 1859, p. 417 *et seq.*

strong arrested its movements altogether. Now in the case of any voluntary muscle the passage of such a current through the nerves supplying it produces either simple contraction, or if the shocks be sufficiently frequent, tetanus, but in the case of the heart the effect produced is, on the contrary, that of complete relaxation. The cessation of the rhythmical action in diastole is not, however, of long duration; contraction soon recommences, notwithstanding the continued application of the electrical stimulus, though it can be again arrested, or materially retarded, by passing the interrupted current through a fresh portion of the nerve situated lower down or nearer the heart. This recommencement of the heart's action is probably, as Rutherford first pointed out, the result of the accumulation of blood in the right cavities of the heart.* Comparative trials showed that a very much stronger stimulus is necessary so to excite the Cardio-inhibitory fibres of the Vagus that the heart's action may be arrested than is required to stimulate such a nerve as the recurrent laryngeal fibres, so that the laryngeal muscles may be thrown into action.† The woodcut (Fig. 129) will show by means of a tracing the effect of stimulation of the lower end of the Vagus in the rabbit. It will be observed that the undulations, each of which represents a cardiac contraction, are very rapid and small till the moment at which the stimulus is applied to the Vagus. They then become much slower, and larger, whilst their mean level falls, indicating a diminution of blood-pressure. As soon as the stimulus to the Vagus is withdrawn the contractions present their former frequency, and the blood-pressure again rises. Further inquiry by Cyon and Ludwig‡ soon showed that in the rabbit the Vagus gives off a branch immediately below the inferior laryngeal nerve, which may be called the Cardio-inhibitory of the Vagus (see Fig. 128), since, when excited, it is capable of exerting the same controlling, restraining,

Fig. 128.

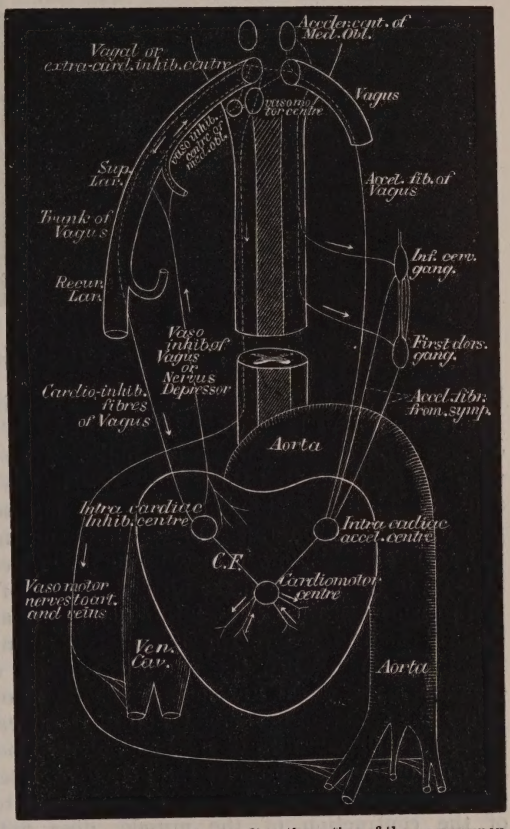

Diagram to aid in understanding the action of the nerves upon the Heart. The Right half represents the course of the inhibitory, and the Left the course of the accelerating nerves of the Heart; the arrows showing the direction in which impressions are conveyed. The ellipse at the upper extremity of the Vagus looking like the section of the nerve is intended to represent the Vagal nucleus or centre. In this diagram the nerves are incorrectly made to cross, instead of passing behind, the aorta.

arresting, or inhibitory power over the Cardiac movements as the Vagus itself. In man this nerve is represented by the superior Cardiac branch of the Vagus. If this nerve be divided on both sides and the upper cut surface of the nerve on either side be irritated no effects are produced, but if the lower cut surface

After. During. Before.

Tracing showing effect of stimulation of Vagus. The tracing must be read from right to left. The rise and fall of the tracing as a whole constitute the "respiratory curves."

be irritated, the heart stops in diastole. Slowing of the Cardiac beats occurs if only one Vagus be divided. The fibres of the nerve therefore appear to conduct impulses downwards (as indicated by the arrow in Fig. 128.). It might be supposed that these fibres pass to the Cardio-motor centre, and exert a direct inhibitory influence upon it, but several circumstances render it probable that an intermediate apparatus, or inhibitory mechanism which we may term an inhibitory centre, exists in the heart between the vagal branches running to the heart and the ultimate fibres of these branches. For, in the first place, when the Cardio-inhibitory nerves are stimulated a very appreciable interval elapses before the inhibitory action is manifested. Thus Pflüger found that even when the stimulus applied was strong enough to produce complete arrest of the Cardiac movements, two entire beats always intervened before the cessation occurred,* and in Donders' experiments, a period of 0·17 sec., or nearly one-fifth of a second, elapsed before arrest occurred. But in the case of ordinary muscles the period of latent excitation, or the time that elapses between the application of a stimulus to the nerve and the beginning of the contraction of the muscle, does not exceed 1–100 of a second. The long "latent period" seems to indicate that there are resistances to be overcome, and that the action of the stimulus is indirect. Secondly, Meyer† has been able by direct irritation of a particular part of the sinus venosus in the common eel by means of an interrupted current to arrest the heart's action for sixteen minutes, and in the frog he was occasionally able by persistent direct irritation to keep the heart at rest for an hour. Prof. Foster,‡ again, has pointed out that in certain Molluscs there is no nerve corresponding to the Vagus, but that the heart can be stopped in diastole by

* Pflüger found that the first perceptible effect of slight irritation of the Vagi is a prolongation of the diastole of the heart, or a retardation of the motor impulse, inducing the next contraction. When violent or long-continued excitation is applied to the Vagi, producing stoppage of the heart's action, the first beats on its recovery are usually very feeble; but when only moderately strong currents are applied, the first beats are often as energetic or even more powerful than before. This would seem to show that if the inhibitory influence is very strongly exerted it prevents the production of motor energy in the motor ganglia, whilst if it be moderately excited it does not interfere with its generation, but only with its discharge.

† "Das Hemmungsnerven-system," 1869.

‡ Pflüger's "Archiv f. Phys.," Band v. p. 191.

direct irritation when removed from the body. The inhibitory mechanism must in these instances be in the heart itself.

Evidence of an intermediate apparatus such as is represented in the above Figure as the intra-cardiac inhibitory centre is also derived from the action of certain poisons.* Thus Nicotin and Curare when injected subcutaneously in very small doses (1-8th to 1-3rd of a milligram) appear to stimulate the inhibitory centres, and the heart beats slower; but they soon paralyse these centres, and the heart then beats faster, and when this occurs irritation of the Vagus will no longer inhibit the heart's action, but if whilst the heart is beating faster Muscarin or Jaborandi be administered or the sinus venosus be irritated the heart still stops in diastole. The effects of Atropin are remarkable, for if a small quantity be injected subcutaneously the heart immediately begins to beat more rapidly, but its condition so far differs from its increased action under Nicotin that it can no longer be stopped in diastole by irritation of the sinus venosus, or the administration of Muscarin. The explanation of this appears to be that whilst Nicotin and Curare in certain doses and stages of their action paralyse the vagal centre, and the cardio-inhibitory fibres of the Vagus, so that these can no longer transmit inhibitory impulses, they do not paralyse the Intra-cardiac inhibitory centres, as is indicated by the effect of direct irritation on the sinus venosus. Atropin,† on the other hand, not only paralyses the vagal inhibitory centre, but it also paralyses the intra-cardiac inhibitory centres, for the heart under its influence is no longer capable of being arrested in diastole, either by irritation of the vagus or of the sinus venosus.‡ Dr. Brunton is disposed to think that Atropin acts especially on the connecting filaments, C F, between the inhibitory and cardio-motor centres.§ Continued stimulation of one Vagus annuls or prejudices the inhibitory action of the other.‖ In the course of an elaborate series of experiments upon the action of the nerves on the heart, v. Bezold observed that in animals under the influence of Curare, in which therefore all muscular movements that might complicate the phenomena were prevented, on applying electrical excitation to the upper cut surface of the divided Vagus, the blood-pressure fell, and he also observed that similar irritation applied to the medulla oblongata caused considerable elevation of blood-pressure, which still occurred, even when the two Vagi had been divided. He concluded that the spinal cord contained fibres acting directly on the heart. He further noticed that on division of the spinal cord in the cervical region the blood-pressure immediately fell, whilst if the posterior cut surface of the cord was irritated the blood-pressure again rose. Ludwig and Thiry on repeating v. Bezold's experiments substantiated their accuracy, and noticed that even when all the fibres passing from the spinal cord to the heart were destroyed by means of a galvano-caustic wire, the effects observed by v. Bezold to result from irritation of the cord could still be manifested. They concluded that the rise in the blood-pressure and augmentation in the frequency of the beats of the heart, were due to the constriction of the small vessels in the body generally, and in this conclusion they were supported by the results of ligatures applied to the aorta or larger arteries. Further investigations, the details of which were published in Ludwig's "Arbeiten" in

† If, however, Curare be given in excess of a certain dose, stimulation of the Vagus causes acceleration of the pulse. See Böhm, "Archiv f. Experiment. Pathol.," Band iv. p. 351.

‡ The effect of the administration of Atropin in man is to raise the number of the pulse from 72–80 to 140–180 in the minute. § "Brit. Med. Journ.," Dec. 16th, 1871, p. 689.

‖ Gamgee and Priestley, Foster's "Journ. of Physiology," vol. i. p. 40.

1866, enabled them to announce their discovery of the functions of a small nerve given off from the vagus, and to which they applied the name of *Nervus Depressor*. This nerve arises in the rabbit from the vagus, immediately below the superior laryngeal nerve, from which it often receives a reinforcing filament; and descending through the neck it is distributed to the heart. If this nerve be divided and the lower cut surface be stimulated, no effects are observed; but if the upper cut surface be irritated, an inhibitory action on the heart, together with a marked diminution of pressure in the whole arterial system, immediately becomes manifest, and the animal gives indications of pain. The direction in which it conducts impulses is therefore exactly the opposite to that of the cardio-inhibitory nerve of the Vagus—it is an afferent nerve. If the application of the stimulus be continued, the slight slowing action on the heart passes off, but the blood-pressure continues to fall till it only reaches two-thirds or one-half of its ordinary amount. The fall of the blood-pressure in the above experiment is small if the splanchnic nerves be divided before the application of the stimulus to the depressor nerve. The explanation of these phenomena seems to be that when a stimulus is first applied to the depressor nerve, an impulse is conducted to the vagal centres, from whence an inhibitory influence is directed through the cardio-inhibitory nerves to the intra-cardiac inhibitory centre, and the heart is slowed; but the depressor nerve also contains fibres which exert a restraining or inhibitory power over a vaso-motor centre in the medulla oblongata. Under ordinary conditions a nervous influence is discharged from the vaso-motor centre by fibres which, descending along the spinal cord, emerge with the several roots of the spinal nerves, enter the splanchnics, and are distributed to the smaller vessels throughout the body (one only being shown in Fig. 128). This nervous influence maintains the vessels in a state of permanent tonic contraction, which keeps up the blood-pressure to its normal height. But when the *depressor nerve* is stimulated, an impulse is conveyed to a vaso-inhibitory centre of the medulla oblongata, which re-acting on the vaso-motor centre inhibits its action, and the downward current from this through the spinal cord being consequently arrested, the great system of abdominal vessels dilates and the blood-pressure sinks. The result of this again is that the medulla receives less blood, the vagal inhibitory centres consequently become less active, whilst the heart resumes its ordinary activity. If, however, the splanchnics be first divided the arterial pressure is already greatly reduced in consequence of the extreme dilatation of the abdominal vessels, and the stimulation of the depressor nerve necessarily fails to exert any influence upon them; the blood-pressure therefore remains unchanged. It has been pointed out by Dr. Rutherford, that the inhibitory fibres of the vagus may be excited to action by stimulation applied to: 1. The central end of the vaso-inhibitory or superior cardiac branch of the vagus (depressor nerve); 2. The central end of the vagus of the opposite side; 3. Almost any sensory nerve in the case of warm-blooded animals, the fifth (according to Hering and Kratschner) having a very special action; 4. The abdominal viscera in the frog; 5. The splanchnic and cervical sympathetic. In these instances the cardio-inhibitory nerves appear to be excited in a reflex manner. The inhibitory action of the *right* Vagus upon the heart is much more marked than the left in the tortoise.* It may just be noticed that both Dr. Rutherford and Dr.

* Meyer (Op. cit.). In pigeons and rabbits Masoin (Op. cit.) and Arloing and Tripier (Op. cit.) state that of the left is greatest. Though coursing in the trunk of the vagus, the inhibitory nerves seem really to be derived from the spinal accessory, since if the fibres of the spinal accessory which Bernard has shown spring from the medulla oblongata and join

Coates,* of Glasgow, have shown that irritation of the vagus always diminishes the absolute amount of work done by the heart. A difference exists between the action of the vagi on the heart in the Frog and in mammals. If in the Frog one vagus be stimulated till it is exhausted and the heart begins to act again, stimulation of the other vagus causes prolongation of the diastole. But in mammals under the same circumstances, when the stimulus is applied to the second vagus, the heart instantly *pulsates*. This has been termed the "interference action" of the vagi.† Schiff‡ finds that if the heart be made to work with a ·6 per cent. solution of common salt or phosphate of soda, the inhibitory action of the vagus is lost, but returns when blood is readmitted.

227. There is reason to believe that the depressing effects of *shock* may be exerted both through the vagus and through the sympathetic system of nerves, and that considerable disturbance may ensue from lesions of such branches of these nerves as are most nearly connected with the heart. For the well-known fact of sudden death not unfrequently resulting from a blow on the epigastric region, especially after a full meal, without any perceptible lesion of the viscera, seems to indicate that a violent impression upon the widely-spread cœliac plexus of Sympathetic nerves (which will be much more extensively communicated to them when the stomach is full, than when it is empty), may cause the immediate cessation of the heart's action probably by a reflex action conducted to the cord and reflected through the pneumogastrics to the heart, in the same manner as a severe injury of the brain or spinal cord. This effect is not observed if the two vagi or the medulla be divided. A case has been put on record, in which the heart's pulsations were occasionally checked for an interval of from 4 to 6 beats, its cessation of action giving rise to the most fearful sensations of anxiety, and to acute pain passing up to the head from both sides of the chest—these symptoms being connected, as appeared on a post-mortem examination, with the pressure of an enlarged bronchial gland upon the great cardiac nerve.§ Czermak‖ has produced all the usual effects of irritation of the vagus in his own person by carefully-applied pressure over the vagus in the neck.

228. *Nerves Accelerating the Action of the Heart.*—The action of the heart cannot only be rendered slower or stopped by irritation of certain fibres running in the vagus, but by the irritation of other nerves its movements can be accelerated. V. Bezold observed that irritation of the cervical sympathetic is followed by increased frequency of the heart's beats, but that this effect is not constant.¶ Much more marked increase follows irritation of the communicating filaments running between the spinal cord and the inferior cervical and first dorsal ganglia of the sympathetic. Irritation of the spinal cord

the vagus, be torn out, it will be found impossible to arrest the heart's action by irritation of the vagus trunk, even as early as three days after the operation, that is, before degeneration of the nerve's fibres could have set in (Brücke, "Vorlesungen," 1874, Band ii. p. 94), though it can be immediately produced by irritation of the opposite vagus.

Sachs.-Gesell. d. Wiss.," 1866, and "Comptes Rendus," 1867, pp. 670 and 1049; Karl Bever, "Würzburg Medicin. Zeitsch.," Band vii. p. 215; Rutherford, "Transact. Roy. Soc. Edin.," 1870, vol. xxvi. p. 1, and his excellent Lectures in the "Lancet," in 1871–72.

itself, and of the medulla oblongata, causes increased frequency of the pulse, though this has been shown by Ludwig and Thiry to be a complicated phenomenon, and due in part to the effect of such irritation in producing contraction of the smaller arteries. The accelerating fibres, however, seemed from their observations to arise from centres in the medulla oblongata and spinal cord,* and emerging from the latter by the rami communicantes to enter the sympathetic ganglia, and to proceed from thence to the heart (see Fig. 128, right side). This view is supported by the experiments of v. Bezold and the brothers Cyon,† who have eliminated the influence of vascular innervation by division of the spinal cord between the first and second dorsal vertebra. The vessels are then permanently paralysed; but irritation of the spinal cord in the cervical region will still be found to produce considerable increase in the frequency of the pulse, though the variations of blood-pressure are slight or nil. Cyon believes that two accelerating branches are given off from the first thoracic ganglion. The course of the accelerating fibres has been much elucidated by the careful dissections of Schmiedeberg‡ made upon the dog. In this animal the vagus and sympathetic run together as far as the inferior cervical ganglion. Here they separate, and the vagus then gives off the recurrent laryngeal. The last cervical and first dorsal ganglion of the sympathetic are connected by two filaments, the upper one of which often joins the vagus. The inferior cervical ganglion gives off the superior cardiac nerve, and sometimes the inferior cardiac, though both not unfrequently come off from the vagus. One of them is sometimes absent, and both appear to act as accelerators (though they sometimes contain inhibitory fibres) and to reach the sympathetic through the roots connecting the sympathetic with the cord. In the Rabbit, the fibres directly accelerating the action of the heart proceed from the medulla oblongata, or possibly from the brain, and descending through the cervical portion of the cord, emerge as in the dog, opposite the inferior cervical and first dorsal ganglion of the sympathetic which they enter, and then proceed to the heart. In the Cat the accelerating fibres run chiefly in the right vagus.§ Stricker and Wagner‖ maintain that they descend from the medulla oblongata through the spinal cord as low as to the sixth dorsal vertebra, and that they pass out by the *rami communicantes* which connect the dorsal nerves with the sympathetic trunk. They then traverse the *ganglion stellatum* or first thoracic ganglion, and enter the Ansa Vieusenii, from whence they pass to the heart. Hence section of the rami communicantes or of the Ansa Vieusenii slows the heart. Schiff¶ denies the existence of accelerator nerves either in the cervical portion of the spinal cord or in the sympathetic. He derives them from the spinal accessory nerve, and believes that they run chiefly in the right vagus. He has not observed any retardation of the heart's action after section of the rami communicantes or of the Ansa Vieusenii. In the Frog the vagus contains accelerating as well as inhibitory fibres, for Wündt** has shown that, at a certain stage of poisoning with Curare, irritation of the vagus no longer causes slowing but quickening of the heart's action; and the same has been noticed in the action of Atropin and Nicotin. On grounds similar to those

* And one may possibly be situated even in the brain, since a larger region of the cerebral surface causes, when stimulated, increased frequency of the pulse. Schiff, "Jahresber. f. Anat. u. Physiol.," Band iii. Abth. iii. p. 31.

which have led to the admission of an intra-cardiac inhibitory centre, the existence of an intra-cardiac accelerator centre, or series of centres, seems probable. The accelerating fibres appear to be less easily excited and less readily exhausted than the inhibitory fibres.* They render the contractions of the heart more sudden as well as more frequent but less powerful.† The latent period is very long, amounting even to 10 seconds. Schiff finds that if the blood of frogs be replaced with a saline solution in Cyon's method the inhibitory power of the vagus is abolished, whilst its accelerating is retained.‡ Baxt§ has investigated the influence of the duration of the stimulus in cases of maximum stimuli. The duration of the application of the current lasted from 1 to 36 seconds, and in all instances the vagi were divided and the animals moderately curarized. The absolute number of beats induced by maximum stimuli was almost entirely independent of the duration of the stimulus, and of the previous and very varying rapidity of the action of the heart, whilst it was remarkably constant in the same animal. Further, the rapidity with which the maximum frequency of beat is attained is independent of the duration of the stimulus. Thus, after the application of a stimulus lasting only 1 second, the heart attains its maximum frequency of action in from 8-10 seconds, which is quite as rapidly as when the stimulus is applied for a longer period, but the effect lasts a much shorter time.

229. During the last few years the action of numerous poisons on the heart has been made a subject of special investigation, but the results at present obtained scarcely admit of being accurately classified. Some appear to act as paralysers, others as excitors of the motor and inhibitory nerves respectively; others, as the sulphocyanide of potassium,‖ act directly on the muscular tissue, rendering it incapable of responding to the strongest stimuli. And others, again, indirectly influence the force and frequency of the heart's action by their action on the respiratory, or upon the vaso-motor systems of nerves. When it is remembered that different animals are not affected in the same manner by particular poisons, and that there is frequently a difference between the effects of large and small doses, it may be conceived that the difficulty of explaining the phenomena observed is extreme. It may be observed, however,¶ that some poisons, as the Antiaris toxicaria;** Tanghinia venenifera;†† Digitalis; Helleborus niger; Helleborus viridis; the green resin obtained from the Nerium oleander;‡‡ Squill; Manganja, from the Zambesi river (Dr. Sharpey); and Carroval and Vao, from the river Darien;§§ most of which have been examined by Drs. Fagge and Stevenson, produce in frogs a peculiar form of irregularity in the action of the heart, attended with protrusion of its walls at different points, and acceleration of its beat; then diminished frequency, caused by protraction of the ventricular systole;

* And in support of this Mitchell and Morehouse ("Smithsonian Contribution to Knowledge," Washington, 1863, p. 37) state that in Chelonians whilst galvanization of the vagus arrests the heart's movement, gentle irritation causes the heart to beat more rapidly.

and, finally, stoppage of the contractions by cessation of the dilatation of the ventricles, which remain contracted, white, and perfectly empty. The stoppage usually occurs in from five to twenty minutes after the administration of the poisonous dose, and the animal retains its control over the voluntary movements for a quarter of an hour or more after the heart has ceased to beat. Calabar bean, on the other hand, according to Dr. Fraser, is a poison that produces cardiac paralysis in an exactly reverse manner. It causes no acceleration, but exciting the vagal centres it diminishes the frequency of the contractions by prolonging the ventricular diastole; and it produces the final stoppage by cessation of the contraction of the ventricles, which then remain dilated, dark, and full of blood.* The Atropin group of bases—viz., atropin, hyos-

* Arsenious acid (Cunze, "Zeits. f. Rat. Med.," Band xxviii. p. 33, and Sklarek, Reichert's "Archiv," 1866, p. 481), bromide of potassium (Eulenberg and Guttmann, "Compt. Rend.," 1867, p. 1281), the salts of barium and of oxalic acid (Cyon, Reichert's "Archiv," 1866, p. 196), chloroform (P. Q. Brondgeest, "Nederland. Arch.," 1865, p. 473, and Dogiel, Reichert's "Archiv," 1866, pp. 231 and 415), nicotin, quinine (Eulenberg, "Compt. Rend.," 1867, p. 421, Solyet, ibid. 1867, p. 719), strychnia (Heineman, Virchow's "Archiv," xxxiii. p. 394), the arrow poison of Borneo (Braidwood, "Edin. Med. Journ.," Aug. 1864), aconitina (Achscharumow, Reichert's "Archiv," 1866, p. 281), caffein and thein (Leven, in "Archives de Physiologie," 1868, p. 481), delphinin (Böhm, "Centralblatt," 1871, p. 586), muscarin (Schmiedeberg, Ludwig's "Arbeiten," Band v. 1871, p. 41, and Band vi. 1872, p. 34), and the gases sulphuretted hydrogen (Kaufmann and Rosenthal, Reichert's "Archiv," 1865, Heft 6), hydrocyanic acid (Preyer, "Archiv f. Path. Anat.," Band xl. p. 125), carbonic oxide (Pokrowsky, ibid. 1866, Heft 1, and Traube, "Cbl.," No. 10, 1866), carbonic acid (Cyon, "Compt. Rend.," 1867, p. 1049), or blood saturated with them, seem all to exercise a depressing influence upon the motor ganglia of the heart, causing it to stop in diastole, in some instances (aconitina) with, in other (delphinin) without, a preliminary stage of accelerated frequency of beat and augmented blood-pressure. When the stoppage in diastole is sudden, as occurs when blood charged with carbonic acid is transmitted through the heart, the effect may with probability be referred to direct stimulation of the extremities of the pneumogastric or inhibitory nerves. Cinchonin accelerates the action of the heart (Elson, "Amer. Journ. of Med. Science," 1866, July, p. 9). Atropin (v. Bezold and Blöbaum, "Unters. aus der Physiol. Labor. zu Würzburg," 1867, p. 1) paralyses the terminal branches of the vagus in the heart. The feeble influence exerted by the vagus over the cardiac movements in rabbits explains in part their immunity from the injurious effects of large doses of the poison (see Dr. Ogle, "Med. Times and Gaz.," 1867, p. 466). For other papers on the action of poisons on the heart, see Boehm ("Studien üb. Herzgifte," Pamphlet, and Abstract in "Centralblatt," 1871, p. 584), Basch and Oser ('Wirkungen des Nicotins,' "Wien. Med. Jährb.," 1872, p. 367), Polaillon et Carville ("Les Effets Toxiques de l'Inée, Poisons de Pahoions"), Gabor ("Archiv d. Physiol.," 1872, pp. 523 and 680), Ackermann ('Wirkungen des Digitalins,' "Deutsche Archiv f. Klin. Med." 1872, Band xi. 125), and Volkmann's "Sammlung Klin. Vorträge," No. 48; Brunton ("On Digitalis," 1868), Fothergill ("Digitalis" 1871), Oulmont and Laurent ('On Hyoscyamin and Daturia,' "Archiv. de Physiol.," Nos. 2 and 3, 1870), Holmes ('On Ergot,' "Arch. de Phys.," 1870, p. 384), Fick ('Die Wirkung des Sparteins,' "Archiv f. Experiment Path.," Band i. 1873, p. 397), Nunneley ("Proc. Roy. Soc.," June, 1869, and "Practitioner," 1869, p. 347, action of atropin, digitalin, aconitin, strychnia, veratria, morphia, nicotin, conium, and bromide of potassium), Arnstein and Sustschinsky, 'Ueber die Wirkung des Calabar auf die Herznerven,' in "Würzburg Phys. Untersuch.," Band iii.), Buchheim and Loos ("Neb. die Pharm. Gruppe des Curarins," Pamphlet), Wood, 'Viridia and Veratroidia,' "Amer. Journ. of Med. Much discussion has arisen in regard to the question whether the inhibitory power of the pneumogastric nerves upon the heart is affected by the administration of curare, Bernard ("Leçons sur les Effets des Substances Toxiques," 1857, pp. 348, 352, 373), Kölliker (Virchow's "Archiv," Band x. 11, 17, 39, 73, and "Med. Central Zeitung," 1858, No. 58), Heidenhain ("Allg. Med. Central Zeit.," 1858, No. 64), Funke ("Lehrbuch," 4th edit. 1863, pp. 959 and 979), Goltz (Virchow's "Archiv," Band xxvi. p. 24), and Budge ("Physiologie," 1862, p. 549), considering it to be proved that these nerves are rendered incapable of transmitting their inhibitory influence; whilst v. Bezold ("Central. Zeit.," 1858, Nos. 49 and 59), Vulpian ("Gaz. Méd. de Paris," 1858, No. 27, p. 429), Meissner ("Zeits. f. Rat. Med.," 3 R., Band vi. p. 506), Bidder (Reichert's

cyamin (which is an atropin containing 1 eq. of methyl ammonium instead of 1 eq. of hydrogen), conium, daturin, together with physostigmin, aconitin, delphinin, and veratrin first, or in small doses, stimulate, and then *lower* or *abolish* the excitability of the inhibitory centres.* The intra-cardiac inhibitory centres are stimulated by muscarin, and with suitable arrangements to prevent desiccation the heart of a frog may be kept motionless in diastole for hours under its influence, but if it be acted upon by a solution of atropin it soon again resumes its ordinary movements. Referring to Fig. 128, it may be said that the cardio-inhibitory fibres of the vagus are excited by nicotin and paralysed by curare, that the intra-cardiac inhibitory centre is excited by muscarin, and that the connecting filaments, C, F, between the intra-cardiac inhibitory and motor centres are paralysed by atropin and excited by Calabar bean.

230. There seems adequate reason to believe that the whole, or very nearly the whole, of the blood contained in the Ventricles is discharged from them at each systole; for the left ventricle is very frequently found quite empty after death; and if a transverse section be made through the heart, when in a state of well-marked *rigor mortis* (which may be considered as representing its ordinary state of complete contraction), the ventricular cavity is found to be entirely obliterated.† The total quantity discharged from either ventricle of the Human heart at each systole is estimated by Valentin at 5·3 oz., by Volkmann at 6·2 oz., and by Vierordt at 6·3 oz.; but these amounts are deduced from calculation of the (supposed) total of the blood, divided by the estimated duration of its passage through the heart, rather than from actual admeasurement. The time occupied by the Blood in making an entire circuit of the body was attempted to be ascertained by Hering,‡ by introducing prussiate of potash into one part of the system, and drawing blood from another. He states that he detected this salt in blood drawn from one of the jugular veins of the Horse in about 30 seconds after it had been introduced into the other; in which brief space the blood must have been received by the heart, have been transmitted through the lungs, have returned to the heart again, have been sent through the carotid artery, and have traversed its capillaries. These experiments have been fully confirmed by those of Poiseuille,§ and of Mr. Blake,‖ who found that a solution of nitrate of baryta injected into the jugular vein of a Horse appeared in the blood of the carotid artery of the opposite side after an interval of 15 seconds. The same inquiry has been pursued, with improved means, by Vierordt.¶ This observer affixed a number of small cups to a drum which was made to rotate at a certain velocity in front of the opened vein; analyses of the contents of the several vessels enabled him to ascertain with great accuracy the moment at which the salt injected made its appearance. In this way he determined the number of seconds occupied by the blood in performing one entire revolution to be, in Squirrels 4·39, in Cats 6·69, in the Hedgehog 7·61, in Rabbits 7·79, in the Dog 16·7, in the Horse 31·5, in the Cock 5·17, in the Duck 10·64, and in the

"Archiv," 1865, No. 3, p. 337), contend that this agent does not paralyse the vagi, no loss of regulatory or inhibitory power being observable between poisoned and healthy animals. Bidder arrived at the latter conclusion in reference to the splanchnic nerves, and their influence upon the intestines. He noticed also, in opposition to Kölliker, that in poisoning by curare great dilatation of the pupil, indicating the persistence of the agency of the sympathetic, occurred, and he perceived no indications of paralysis of the vaso-motor nerves. This contradictory testimony is probably referrible to differences in the composition of the poison and in the quantity administered.

Goose 10·86. He estimates the period in Man at 23·1 seconds (during which there are 28 beats of the heart), of which 2 seconds at most are occupied in traversing the larger arteries, 2½ to 3 seconds in passing through the smaller arteries, 3 seconds for the capillaries, and 4 or 5 seconds for the venous system, which numbers must be multiplied by two for the two circulations. Moreover, the coincidence between the cessation of the heart's action, and the diffusion of the salt through the arterial blood, bears a striking correspondence; and it may be hence inferred that the arrestment of its muscular movement is due to the effect of this agent upon its tissue, when immediately operating upon it, through the capillaries of the coronary artery.—This conclusion is borne out by a variety of other experiments, which show that the time of the agency of other poisons that suddenly check the heart's action (which is the special property of *mineral* poisons), nearly coincides, in different animals, with that which is required to convey them into the arterial capillaries. And it seems to derive full confirmation from the fact, that poisons which act locally on other parts give the first indications of their operation in the same period after they have been introduced into the venous circulation. Thus, in the Horse, the time that is required for the blood to pass from the jugular vein into the capillary terminations of the coronary arteries is 16 seconds, as is shown by the power of nitrate of potash to arrest the heart's action within that time; and nitrate of strychnia, injected into a vein, gave the first manifestation of its action on the Spinal Cord in precisely the same number of seconds. In the Dog, the heart's action was arrested by the nitrate of potash in 11 or 12 seconds; and the tetanic convulsions occasioned by strychnia also commenced in 12 seconds. In the Fowl, the former period was 6 seconds, and the latter 6½; in the Rabbit, the first was 4, and the other 4½ seconds.—From such experiments it seems evident that the rapidity of the circulation is underrated, in any estimate that is founded upon the capacity of the Heart, and its number of pulsations in a given time; and it is difficult to see how the two sets of facts are to be reconciled. According to Hering, the rapidity of the circulation diminishes with age; and Vierordt has shown that with increased frequency of the heart's action there is in general an increased rapidity of the circulation, at least in the higher Vertebrata. Still it by no means follows that an increase in the frequency of the heart's action in a particular animal should be always accompanied by an increased rapidity in the current of the circulation; in point of fact, the experiments of Hering* show that, in the Dog and Horse, when inflammatory or febrile conditions, such as Pericarditis, are set up, a much longer period is occupied in the passage of the blood than before.

231. The *number* of contractions of the Heart in a given time is liable to great variation, within the limits of ordinary health, from several causes; the chief of these are diversities of Age, of Sex, of Stature, of Muscular exertion, of the activity of the Respiratory process, of the condition of the Mind, of the state of the Digestive system, and of the Period of the day.

a. Putting aside the other causes of uncertainty, the following Table may be regarded as an approximation to the average frequency of the Pulse, at the several *Ages* specified in it, taking equal numbers of Males and Females.

† The rise in the average frequency of the pulse in very advanced life, contrary to the

b. The difference caused by *Sex* appears from the inquiries of Dr. Guy,* to be such, that the pulse of the adult Female is more frequent than the pulse of the adult Male, at the same mean age, by from 10 to 14 beats in a minute.

c. The influence of *Stature* is affirmed by Volkmann to be tolerably well defined. The pulse being *cæteris paribus* less frequent as the stature is greater; so that if the pulse of a man of $5\frac{1}{2}$ feet high were 70 per minute, that of a man of 6 feet would be 66·7, and that of a man of 5 feet, 73·8.

d. The effect of *Muscular Exertion* in raising the pulse is well known; as is also the fact, which is one exemplification of it, that the pulse varies considerably with the *posture* of the body. The amount of this variation has been made the subject of extensive inquiry by Dr. Guy; and the following are his results:—In 100 healthy Males, of the mean age of 27 years, in a state of rest, the difference between standing and sitting was 10 beats, or about 1–8th of the whole number of beats per minute; the difference between sitting and lying was 5 beats, or 1–13th of the whole; and the difference between standing and lying was 15 beats, or 1–5th of the whole. In 50 healthy Females of the same mean age, the difference between standing and sitting was 7 beats, or 1–13th of the whole; that between sitting and lying was 4, or 1–24th of the whole; and that between standing and lying was 11, or 1–8th of the whole. Dr. Ed. Smith has made similar and very extended observations on Adults in Phthisis and on Children in health; and conjoined with them the influence of period of the day. He found in Phthisis, at 8 A.M., the increase, on assuming the sitting and standing postures, was in each case 10 pulsations per minute, but at 4 P.M. it was reduced to 7, and on the whole average there was an increase of $8\frac{1}{2}$ pulsations in each posture. In healthy Children, at 8 A.M., 12 (noon), 5 P.M., and 8 P.M., the increase in the sitting posture was 1 2 : 9 : 7·3 : 3·5 pulsations, whilst in the standing posture it was 27 : 14·6 : 12 : 10 pulsations per minute: results which seemed to show that the irritability of the heart, augmented by the rest and quiescence of sleep, undergoes a gradual diminution through the day. In both sexes, the effect produced by *change* of posture increases with the usual frequency of the pulse, whilst the exceptions to the general rule are more numerous, as the pulse is less frequent. The variation is temporarily increased by the muscular effort, involved in the absolute change of the posture; and it is only by the use of a revolving board, by which the position of the body can be altered, without any exertion on the part of the subject of the observation, that correct results can be obtained. That the difference between standing and sitting should be greater than that between sitting and lying, is what we should expect, when we compare the amount of muscular effort required in the maintenance of the two former positions respectively. A different explanation has, however, been offered by Ludwig, who considers that the slowing of the pulse which occurs in the recumbent position is due to excitation of the vagal roots from increased blood-pressure in the medulla, and Dr. Brunton has observed that if whilst in the recumbent position the head be held much lower than the body the pulse becomes greatly accelerated, possibly from excitation of the accelerator centres in the medulla. It is stated by Lichtenfels and Frölich that the alternate contraction and relaxation of any set of muscles has a much greater effect than their simple tonic contraction in increasing the action of the heart.†

prevalent notion, has been determined by the observations of Levret and Mitivié ("De la Fréquence des Pouls chez les Aliénés"), Dr. Pennock ("Amer. Journ. of Med. Sci.," July, 1847), and Prof. Volkmann (Op. cit., p. 427).

* "Guy's Hospital Reports," vol. iii. p. 312; and "Cyclop. of Anat. and Physiol.," vol. iv., Art. 'Pulse.' † "Denk. d. kais. Akad. d. Wissens. zu Wien," 1852, t. iii. pt. ii. p. 149.

e. The pulse is well known to be much accelerated by *Mental Excitement*, especially by that of the Emotions; it is also quicker during *Digestion.* The ingestion of warm food produces this effect much more rapidly than cold; and according to Budge,* whilst animal food raises the frequency of the pulse more quickly than vegetable, the effect of the latter is much greater and more permanent. Lichtenfels and Fröhlich found that, an hour and a half after breakfast, the pulse was 13 beats per minute quicker than before, whilst there was only an increase of 9 beats an hour after dinner. The pulse was less frequent in vegetarians, however, than in those who fed on animal diet, and was probably less energetic. The ingestion of large quantities of water diminishes the frequency of the pulse (Bocker). Dr. Ed. Smith ascertained the rate at each hour of the 24 hours for 3 days successively in health, and for 6 days in Phthisis. He found that it was never stationary, but that there was a progressive increase after a meal and decrease before a meal, so that there were four maxima and four minima daily. The maxima occurred about two hours after a meal, and were the greatest after breakfast and after tea. The day minima immediately preceded the meals, and all were nearly equal. The pulse invariably fell after 9 P.M., so that supper produced but little effect; and the lowest point of the 24 hours was from 3 to 5 A.M. There was an increase in the morning with sunlight. The difference between the maximum of the day and the minimum of the night amounted in health to from 14 to 34 pulsations, and in Phthisis to from 22 to 45 pulsations. The increase from that of the night to the breakfast maximum was, on the average, 27 pulsations in phthisis. There was a considerable increase in children whilst eating. During a fast of 24 hours the variation in the rate was small, but there was an increase during the usual meal hours and an increase at night.

f. The pulse varies also with the *Season*, and Dr. Ed. Smith has shown by daily experiments throughout the year that the rate of pulsation is greater in the Spring and Summer than in the Winter, both in health and Phthisis. In experiments made upon Frogs, Budge† and Calliburcés found that immersion of the excised Heart or of the hind legs in warm water increased the frequency of the pulse (§ 243); the same result was obtained after section of the Crural Nerves, or after poisoning by Curare, showing that it was not effected through the cerebro-spinal nervous system.

g. Variations in the pressure of the surrounding atmosphere exert a certain, but not very well-ascertained influence on the frequency of the Pulse. Alpine travellers are well acquainted with the increased rapidity of the pulse which occurs on attaining great heights; but this is probably in great measure attributable to the great muscular exertion previously made. Salvatore Tommasi, however, observed an increase of 8 in the number of his pulsations, after a good night's rest in the Alpi di Susa, at an elevation of between seven and eight thousand feet.‡ In some experiments performed by Vivenot§ on the effects of compressed air, in which the barometer rose from 742 mm. to 1060 mm., the pulse was observed to rise 3.45 beats on an average of 79. After exposure for an hour and a half to the maximum of pressure it rose 6·33 beats, and 7·31 beats on return to the ordinary pressure. In other experiments on the influence of rarefied air, the barometer falling from 758 to 500 mm., there were observed an increase in the amplitude of the radial tracings, as shown by the sphygmograph, indicative of diminution of vascular tension; increased feeling of warmth in the skin, especially of the face; con-

gestion of the conjunctiva; uneasiness in the head, difficulty of thinking, and neuralgic pains in the forehead, neck, and teeth; all which symptoms appeared to arise from derivation of the blood to the cutaneous capillaries. On gradual readmission of the air they soon vanished.*

232. It may be advisable briefly to sum up the circumstances affecting the frequency of the heart's action. As has already been pointed out the heart not only possesses an internal system of ganglia and nerves by which its movements can be maintained and regulated for some time after excision from the body, but it is also under the control of centres situated in the medulla oblongata; and as there is reason for believing that there are both accelerating and inhibitory centres in the heart and in the medulla, it is obvious that great difficulty must exist in determining the cause of any particular variation in the frequency of its beats that may be observed. We have, however, evidence that the heart may be influenced—

A. By conditions affecting the *intra-cardiac motor ganglia*, which may be (1) excited, and the frequency of the pulsations increased—*a*, by heat; *b*, by mechanical, chemical, and electrical excitation; *c*, by increased blood-pressure, which is essentially a mechanical irritant; *d*, by various poisons: or (2) depressed, and the pulsations lowered—*a*, by cold; *b*, by diminished blood-pressure; *c*, by certain poisons, as chloral.

B. By conditions affecting the *intra-cardiac inhibitory ganglia*, these being stimulated and the heart slowed or stopped in diastole by certain poisons (Muscarin) and paralysed by others (Atropin).

C. By conditions affecting the *intra-cardiac accelerator ganglia*, leading to increased frequency of action. At present these cannot be satisfactorily distinguished from those affecting the intra-cardiac motor ganglia.

D. By conditions affecting the cardiac *inhibitory centres in the Medulla oblongata*, such as increased blood-pressure, which acts directly upon them,† or by irritation of the depressor nerve, or of various other sensory nerves, which act upon them in a reflex manner, or by the action of poisons (Digitalis), all of which excite these centres and cause slowing of the heart's action.

E. By certain conditions affecting the accelerator centres in the medulla, as diminished blood-pressure, mental processes, the action of poisons. They may also probably be excited in a reflex manner. It will be seen from the above that certain conditions, increased blood-pressure for example, exerts a double action on the cardiac nerves. On the one hand, it excites the heart to increased

* A. Jaminet, "On the Physical Effects of Compressed Air on Man," &c. (Pamphlet), 1871, pp. 135. Jaminet had the opportunity of examining the effects of compressed air on many workmen engaged in the construction of the Illinois and St. Louis Bridge over the Mississippi River. In this work the men were exposed to a pressure at one time of 50lbs. to the square inch, exclusive of the 15lbs. of the ordinary ambient atmosphere. It was found necessary at an early period to construct an air-lock or intermediate room, where the passage into air or ordinary pressure could be gradually effected, otherwise most serious symptoms, great muscular exhaustion, headache, epigastric pain, sickness, paralysis, hæmorrhage, and even death resulted. M. Jaminet found that increased frequency of the pulse and respiration occurred during the first few minutes, the pulse rising about 15 beats above the normal; but after remaining in the air-chambers for two hours, and whilst still exposed to the action of the increased pressure, the pulse fell about 15 beats below the normal. On issuing into the open air the pulse again rose to 15 or 20 beats above the normal, and slowly in the course of an hour or two returned to its usual state. Glaisher, in his scientific balloon ascents (see his article on Aeronautics in the "Encyclopædia Britannica," 9th edit. 1875, p. 197), found that the pulse, which was 76 before starting, increased considerably at high altitudes, being 90 at 10,000 feet, 100 at 20,000 feet, and 110 at greater heights.

† See Drosdow, "Petersburg Med. Anzeiger," No. 36, 1875; also Tschirjew, Du Bois Reymond's "Archiv f. Physiol." 1877, p. 116.

frequency of action by direct irritation of its motor ganglia through filaments distributed to the Endocardium; on the other hand, it stimulates the vagal centres in the Medulla, and thus causes slowing of the heart, the actual result in any given case being dependent upon the preponderating influence of the cardiac motor or medullary inhibitory centres. Usually the medullary centres are strongest, and increased blood-pressure causes slowing of the heart; but if the vagi be divided, so that they can no longer act on the heart, increased blood-pressure stimulates the heart to more rapid action. The increased rapidity of the pulse observed by Asp to follow excitation of the central extremity of the divided spinal cord has not been found to be constant by Dittmar,* the variation being probably dependent upon the complicated effects of the increased blood-pressure, which the latter experimenter has shown results from this operation.

3. *Movement of the Blood in the Arteries.*

233. The Blood propelled from the Heart is distributed to the body in general by a system of Arteries, which may be likened in its arrangement to the trunk and branches of a tree, except that very frequent communications or anastomoses exist among these branches, so that, by continual subdivision and inosculation, their distribution comes more and more to resemble the capillary network in which they terminate (Fig. 130). Although the *diameters* of the branches, at each subdivision, together exceed that of the trunk, yet there is but little difference in their respective *areas*. What difference does

FIG. 130.

exist, however, is, with few exceptions, in favour of the branches; and thus it happens that there is a gradual increase in the capacity of the arterial system from its centre towards the capillaries, whose capacity is many times greater. In passing from the Capillaries to the smaller arteries, the thin wall of the former, composed of a single layer of cells, becomes strengthened by a second layer of flattened nucleated cells placed externally, and forming a *tunica*

* Ludwig's "Arbeiten," 1871, p. 18.

adventitia; short unstriped muscle-cells also appear, which are at first irregularly distributed, but subsequently form a continuous circular layer—the *Tunica media.* Between the muscle layer and the original endothelial wall of the capillary a delicate hyaline elastic membrane, the *Tunica intima*, can be recognised. In *larger vessels* the tunica adventitia or outer coat is vascular, and composed of connective with much elastic tissue. Surrounding the fasciculi of the connective tissue are lymph spaces, containing branched connective tissue-cells. The tunica media is composed of many layers of short muscular fibre-cells, which in the largest trunks are separated by hyaline elastic membranes and plexuses. Between the outer and middle coat in the larger vessels is a special elastic membrane, the external elastic coat of Henle. The tunica intima is composed of a series of fenestrated laminæ. Between the tunica intima and the endothelium is a membrane composed of connective tissue, named the "subendothelial connective tissue" membrane. Longitudinal muscular fasciculi have been observed in the adventitia of the splenic, renal, femoral, mesenteric, and popliteal arteries; and in the tunica media of the hepatic, splenic, crural, mesenteric and umbilical. Bardeleben, indeed, maintains that all large and middle-sized arteries possess an inner longitudinal muscle-coat.* The adventitia is relatively thickest in the minute arteries. The media is in all arteries the most conspicuous coat. The intima increases in thickness towards the aorta. The endothelium everywhere consists of a single layer of cell plates.†

234. The arteries exert a most important influence upon the movement of the blood through them in virtue of the physical and vital properties of their walls. Their *elasticity*, which is a physical property that persists after death until a serious change takes place in their composition, is due to the elastic fibres their walls contain, whilst their property of *contracting* on the application of a stimulus so long as their vitality remains is attributable† to their muscular coat. These two endowments are possessed in various degrees, proportional to the respective predominance of the elastic or of the muscular tissue, by the different parts of the Arterial system. Thus, as was justly remarked by Hunter, the *elasticity*, being the property by which the interrupted force of the Heart is made equable and continuous, is best seen in the large vessels more immediately connected with that organ; whilst, on the other hand, the *contractility* is chiefly observable in the smaller vessels, where it is more required for regulating the flow of blood towards particular organs. With the exception of the capillaries, *nerves* partly consisting of medullated and partly of pale or non-medullated fibres have been demonstrated in all vessels, even in the non-muscular veins of the pia mater. The fibres,‡ after they have traversed the tunica adventitia, break up into a fine network with here and there ganglionic cells and knots. It is to these ganglionic enlargements that the local contractions of the vessels are due, which take place when the main trunks from the sympathetics supplying them have been divided.

235. The chief purpose served by the *Elasticity* of the Arteries is one of

* See Prof. Kölliker's "Manual of Human Histology" (Sydenham Society's edit.), vol. ii. p. 291, and "Handbuch der Gewebelehre," 5 Auflag. p. 583. Eberth in Stricker's "Human and Comp. Hist.," Syd. Soc. Trans., 1870, vol. i., Art. 'Blood-vessels.' Klein and Noble, "Atlas of Histology."

† Wundt ("Physiologie," 1873, p. 287) finds the co-efficient of elasticity of the arteries (*i.e.*, the weight necessary to be applied to double the length of a given piece) to be 1120 grains, and that of the veins 1465 grains. In both sets of vessels the elasticity is greater in the longitudinal than in the transverse direction. The co-efficient of elasticity of the aorta, taking the mean of several experiments, is 927 grains in the direction of its length and 588 grains in the direction of its breadth, whilst that of the jugular vein is 1503 grains in the former and 725 grains in the latter direction.

‡ Eberth, in Stricker's "Hum. and Compar. Histol.," Syd. Soc. Trans., vol. i. p. 266.

a purely physical character; its effect being to convert the intermittent impulses, which the blood receives from the heart, into a continuous current. The former are very evident in the larger trunks; but they diminish with the subdivision of these, until they entirely disappear in the capillaries, in which the stream is usually equable or nearly so. If a powerful force-pump be made to inject water, by successive strokes, into a system of tubes with unyielding walls, the flow of fluid at the farther extremities of these tubes is as much interrupted as its entrance into them. But if water be forced by a syringe into a long tube of caoutchouc, for example, the stream is found to be equalized before it has proceeded far, owing to that part of the force which is not expended in propelling the fluid, but is employed in stretching the elastic walls, being again restored when the distending force ceases to act. This effect is in fact accomplished, at any part of the Arterial circulation, in a degree proportionate to its distance from the Heart; and in this mode it is, that the intermittent force of the ventricular contraction is almost equably distributed over the whole of the interval between one systole and another, by the contraction of the elastic tubes in the dilatation of which it was at first expended. Another effect of this elasticity is to enable the vessels to accommodate themselves to the various movements of the body and limbs, without interference or obstruction to the current of blood traversing them.

236. The *contractility* of the arteries fulfils several important purposes. It is the principal means by which hæmorrhage from the smaller vessels is arrested after injury, and even in the case of so large an artery as the temporal, the complete division of the tube is often the readiest means of checking the flow of blood. Secondly, under the influence of the nervous system it regulates the supply of blood to the different tissues and organs of the body in accordance with the variations of their functional activity. And, lastly, it enables the whole vascular system to accommodate itself to the very varying amount of fluid it contains at different times, so that the pressure under which it is distributed through the body is approximately the same. It may be readily demonstrated by experiment. Thus, when a ligature is placed upon an artery in a living animal, the part of the artery beyond the ligature becomes gradually smaller, and is emptied to a certain degree, if not completely, of the blood it contained. Again, when part of an artery in a living animal is isolated by means of two ligatures, and is punctured, the blood issues from the orifice, and the inclosed portion of the artery is almost completely emptied of its contents. This contraction is much greater than could be accounted for by the simple *elasticity* of the tissue; and is more decided in small than in large vessels. The empty condition of the arteries, generally found within a short time after death, seems to be in part due to the same cause; since their calibre is usually much diminished, and is sometimes completely obliterated. A remarkable example of the same slow contraction is that which takes place in the end of the upper portion of an arterial trunk, when the passage of blood through it is interrupted by a ligature; for the current of blood then passes off by the nearest lateral branch, and the tube of the artery shrivels and soon becomes impervious from the point at which the ligature is applied back to the origin of that branch. This last fact is important, as proving how little influence the pressure of the blood possesses over the calibre of arterial tubes, since without any interruption to the pressure of blood occasioned by it the tube becomes impervious. Other evidence of the contractility of the arteries may be readily obtained by observing the effects of various stimuli, mechanical, chemical, or electrical, upon the vessels of a transparent membrane, such as the bat's wing or the frog's foot. Thus if,

whilst watching the movement of blood in a companion artery and vein, we draw the point of a fine needle across them three or four times, without apparently injuring them or the membrane over them, they will both presently contract and close; then, after remaining for a few minutes in the contracted state, they will begin again to dilate, and will gradually increase in diameter until they acquire a larger size than before the stimulus was applied. When in this condition they will not again contract on the same stimulus as before; the needle may now be drawn across them much oftener and more forcibly, but no contraction ensues, or only a trivial one, which is quickly followed by dilatation; with a stronger stimulus, however, such as that of great heat, they will again contract and close, and such contraction may last more than a day, before the vessels again open and permit the flow of blood through them.* Further, it has been ascertained by the experiments of Poiseuille (which confirm those of John Hunter), that when an artery is dilated by fluid injected into it, it reacts with a force superior to the distending impulse; and that, if a portion of an artery from an animal recently dead (in which the contractility is preserved), and one from an animal that has been dead some days (in which nothing but the elasticity remains), be distended with an equal force, the former becomes much more contracted than the latter, after the distending force is removed.

237. There is no sufficient proof that the contractility of the arteries enables them to exert a *propulsive* action in any marked degree supplementary to that of the Heart; and yet, looking to the general facts already stated, as to the diffusion of the propulsive power through the arterial trunks in many of the lower animals, their experimentally-proved reaction upon a distending force, and to the circumstance, that a kind of rhythmical action, occurring seven or eight times in the minute, has been observed by Wharton Jones in the vessels of the Bat, by others† in those of the ear and saphenous artery of the Rabbit, which last contracts one or twice in the minute, and in the vessels of the web of the foot in the Frog, it does not seem by any means improbable that some such power should be preserved, even where there is the greatest concentration of the propulsive force in the muscular walls of the Heart. It is important to notice that these systolic and diastolic movements of the vessels are not simultaneous on opposite sides of the body, and that they are quite independent of cerebro-spinal innervation, since they continue even when the whole of the cerebro-spinal and sympathetic nerves have been divided, and even after division of the spinal cord itself in the neck.‡

238. The *influence of the Nervous system* upon the calibre of the vessels, which might be inferred to exist from the act of blushing and other analogous phenomena, is capable of experimental demonstration. Thus the application of a stimulus, such as an induced current of electricity§ to the sympathetic trunk on either side of the neck, causes contraction of the minute arteries on that side of the face, which can be well seen in those distributed to the external

* See Sir James Paget's "Lectures on Surgical Pathology," vol. i. pp. 302, 303.—As Sir James Paget justly remarks, it is from the mechanical stimulus of the knife that small divided vessels contract and close, so as speedily to cease bleeding; but this contraction lasts only for a time; and hæmorrhage would commence on their dilatation if their mouths were not sealed by coagula of blood or lymph. When secondary hæmorrhage does occur from want of such coagulation, it is most effectually controlled by the application of such stimuli as the actual cautery, which induces a more prolonged contraction of the vessels.

ear of the cat or rabbit; whilst, on the other hand, section of this nerve leads to their dilatation. As in the case of the Heart, the nerves supplying the blood-vessels appear to have two centres, one of which is represented by the small ganglia distributed in the walls of the vessels, whilst the other is represented by a centre, or a series of centres, situated in the medulla oblongata and spinal cord. The activity of the *local* ganglia is rendered evident by the contractions that may be produced by direct irritation after division of all the nerves supplying a part. The *central* ganglia governing the contraction of the vessels have received much attention during the last few years,* the general result of which has been to show that an important centre is situated in the medulla oblongata, its lower limit in rabbits being about one-eighth of an inch above the level of the apex of the calamus scriptorius, whilst the upper limit is near the upper border of the corpus trapezoides, just below the corpora quadrigemina. It occupies the antero-lateral part of the medulla oblongata on each side, and corresponds to the continuation through the medulla oblongata of the anterior part of the spinal cord.† In some animals, and especially in the Frog, the vaso-motor centre or centres must extend for some distance down the spinal cord, since on division of the cord in the cervical region which is followed by dilatation of the vessels generally, and by diminution of the blood-pressure in them, section of such a nerve as the sciatic is followed by still further dilatation of the vessels of the posterior limbs accompanied by elevation of temperature. Some experiments of Cyon seem also to show that the vaso-motor centre extends into the brain above the plane of the medulla oblongata. Stricker fixes its limits, in the dog, between the fifth cervical nerve and the first dorsal nerve. This centre exercises a permanent tonic influence on all the smaller vessels, and especially upon the smaller arteries of the body, maintaining their muscular fibres in a state of gentle contraction. It receives centripetal or afferent, and gives off efferent or centrifugal fibres. Both sets of fibres, as Miescher‡ and Nawrocki§ have shown, run in the lateral columns of the spinal cord, and enter into or issue from it with the roots of the several spinal nerves, at least as low down as the eleventh dorsal nerve. They run partly in the sympathetic cords, and partly with the branches of the spinal nerves. Thus the cervical cord of the sympathetic contains the vaso-motor nerves of the skin of the head, the conjunctiva, and salivary glands. The splanchnics, which are exceedingly important vaso-motor nerves, supply the very dilatable vessels of the abdominal viscera. After they have been divided, the abdominal vessels become greatly distended with blood, and retain so much of it in their interior as to lower the pressure in the carotid to a very considerable extent. This effect is

‡ Ludwig's "Arbeiten," 1870, p. 172. § Idem., 1871, p. 89.

not, however, permanent, the pressure rising again as the vessels recover their tone, and by the contraction of their coats drive their contents into the general system again. The contraction is probably attributable to the action of the minute ganglia found in the vascular walls. If, after division of the splanchnics, an electric stimulus be applied to their peripheric extremity, the vessels of the abdominal viscera contract and the blood-pressure in the carotid rapidly rises. The vaso-motor nerve-fibres for the upper extremities pass from the roots of the middle dorsal nerves to the sympathetic cord, and thus reach the first dorsal ganglion, from whence they pass into the brachial plexus (E. Cyon). Those for the lower extremities proceed from the rami communicantes of the sympathetic into the anterior roots of the spinal nerves.* The vaso-motor centre is capable of being excited and of being depressed. In the former case the smaller arteries either of a definite region or of the whole body contract, and the blood-pressure rises. In the latter case the smaller arteries of a territory of variable extent dilate or relax and the blood-pressure falls. This effect is in most instances due to the accumulation of blood in the veins of the abdominal viscera. The excitation of the centre indicated by exaltation of the blood-pressure in the arteries can be effected by the circulation through its vessels of blood charged with carbonic acid or deficient in oxygen, and in a reflex manner by the irritation of almost any of the sensory nerves, as those of the skin,† peritoneal layer of the stomach,‡ dura mater,§ olfactory or nasal nerves‖ (providing the brain is uninjured, Cyon); also by irritation of the cervical sympathetic nerve,¶ and by certain poisons, amongst which digitalis may be particularly mentioned.** On the other hand, the vaso-motor centre can be depressed, or its action inhibited, by irritation of the depressor nerve of the vagus, and fibres having a similar depressing action run in the vagus below the origin of the nervus depressor from the vagus. The *depressor nerve*†† in the Rabbit springs, as already mentioned, by two roots from the superior laryngeal nerve and from the trunk of the vagus, and either runs to the inferior cervical ganglion, or after a short course is blended with the vagus or sympathetic trunk, or passes to the cardiac plexus. If it be divided, stimulation of its central end causes diminution of pressure in the whole arterial system and slowing of the pulse, phenomena that are to some extent independent of each other; for if the pneumogastric be first divided in this experiment no change occurs in the frequency of the pulse,

* The nerves of the vessels supplying a muscle do not always accompany the motor-trunks of that muscle. Thus, the biceps femoris receives its motor nerves from the sacral plexus, but its vaso-motor nerves come from the lumbar plexus through the crural nerve.

Kreidmann, idem, 1878, p. 193, finds anatomical reasons for believing that it forms part of the vagus trunk in man. Baxt, "Ueber die Stellung des N. Vagus zum N. Accelerans cordis. Leipziger Berichte," 1875, p. 323.

whilst the pressure invariably falls. Stimulation of the proximal extremity of the cut depressor nerve is not followed by any perceptible effect.* The nerve seems to act essentially on the vaso-motor centres and not on the heart; since its depressing influence is still observed after division of all the nervous connections between the heart and the brain and medulla, whilst it is scarcely noticeable after division of the splanchnics, since the abdominal vessels are then fully distended. It occurs in curarized as well as in non-curarized animals. It is possible that instead of acting as an inhibitor of the vaso-motor ganglia, it may stimulate the vaso-dilator ganglia, if such ganglia exist; but in either case its action is chiefly exerted on the abdominal vessels and upon those of the inferior extremities, since if the aorta be compressed first below the diaphragm no marked effects are produced. The influence of the depressor nerve in securing a uniformity of pressure throughout the vascular system is sufficiently clear, for if in consequence of stimulation of the vaso-motor centres the peripheric arteries have contracted and the blood-pressure has risen beyond a certain point, this blood-pressure affecting the heart distends its walls and excites the *depressor nerve*. The depressor reacting on the vaso-motor centre in the medulla inhibits its action, which leads to dilatation of the blood-vessels and a fall in the blood-pressure. The term "Traube's curves" is applied to the rhythmical variations of arterial pressure which were observed by Traube† to occur in animals under the influence of Curara during the gradual rise of pressure that arises after complete cessation of the respiratory movements and section of both vagi. Kowalewsky and Adamük and Hering have shown that the rise and fall of pressure constituting Traube's curves are independent alike of variations in the heart's action, and of asphyxia, and that they are referrible to the circulation of non-arterialized blood through the vaso-motor centres, and to variations in the tone of the vessels.

239. There are certain nerves the irritation of which causes dilatation of the vessels to which they are distributed. This is the case with the chorda tympani and with the nervi erigentes of the penis (Lovén), and there is considerable difficulty in explaining their action. The most reasonable view is that of Vulpian, who supposes that there are inhibitory centres in the walls of the vessels which, when irritated, restrain or abolish the tonic influence of the vaso-motor centre, and dilatation is the immediate consequence.‡ Other views that have been advanced are:—1. That of Schiff, who believes it to be possible that certain nerves may, instead of causing contraction, cause elongation of muscular fibres. 2. That which attributes the dilatation of the arteries to increased blood-pressure caused by contraction of the veins; but this is contrary to fact, the veins being dilated in all cases. 3. That of M. Legros,§ who regards active congestion as the result of increased peristaltic contraction of the vessels. 4. That it is due to increased attraction of the tissues for the blood, so that a suction-force or *vis a fronte* is established. Some remarkable experiments bearing on the subject of dilatator-fibres were made in 1876 by Max Frey;‖ who arrived at the conclusion that such fibres were present in the chorda tympani nerve. His method consisted in determining the flow of blood from the divided vessels before, during, and after stimulation of the sympathetic

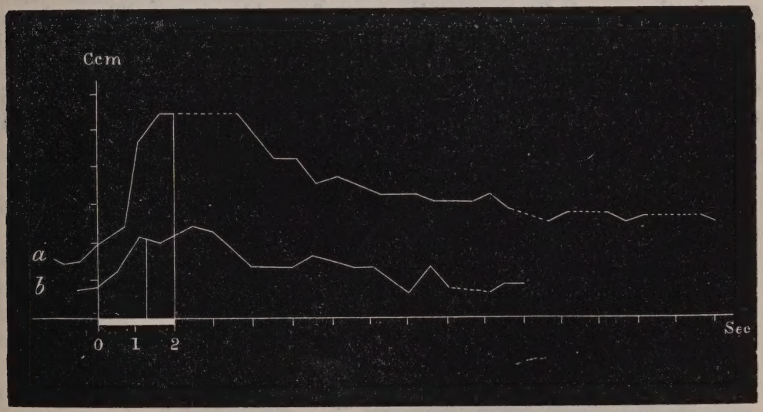
and chorda tympani nerves, and several of his tracings are here given. It is possible that the nerves effecting dilatation of the vessels may exert their

Fig. 131.

The Abscissa is here divided into sections representing ten seconds. The broad white line indicates the period during which a powerful electrical stimulus was applied to the sympathetic nerve. Each millimetre of the ordinals in height corresponds to the discharge of 0·2 cubic centimetre of blood. It will be seen that immediately after the application of the stimulus there was a rise which represents the sudden contraction of the arteries forcing onward their contents; the line then rapidly descends and reaches a minimum which lasts long after the stimulus has ceased to be applied, and rises again by fits and starts. This drawing demonstrates that the stimulation of the sympathetic causes great contraction of the smaller arteries.

influence upon the longitudinal muscular fibres already stated (§ 233) to exist in many arteries. The mode in which variations of pressure affect the pulse has already been explained, § 232.

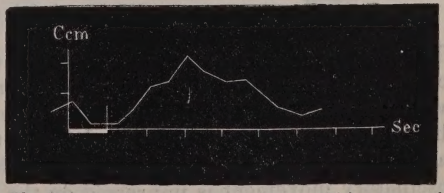
Fig. 132



This Figure shows the effect of powerful stimulation of the Chorda tympani nerve in modifying the discharge of blood from a vessel. The curves *a* and *b* show the results of two successive stimulations of the chorda. The stimulus was applied during the time marked 0 to 2 on the abscissa in the first stimulation, the effect of which is represented by *a*, and from 1 to 2 in the second stimulation, the effect of which is represented by *b*. There is a latent stage varying from 2·5 to 0·1 second in both.

240. The distension of the Arteries that is consequent upon the intermittent injection of blood into their trunks gives rise to the *pulsation* which is perceptible to the touch in all but the smallest arteries, and which is visible to the eye when they are exposed. It would seem to the touch, as if this were chiefly effected by an increase of *diameter*, and the experiments of Volkmann ("Hämodynamik") led him to believe that the transverse dilatation is greater

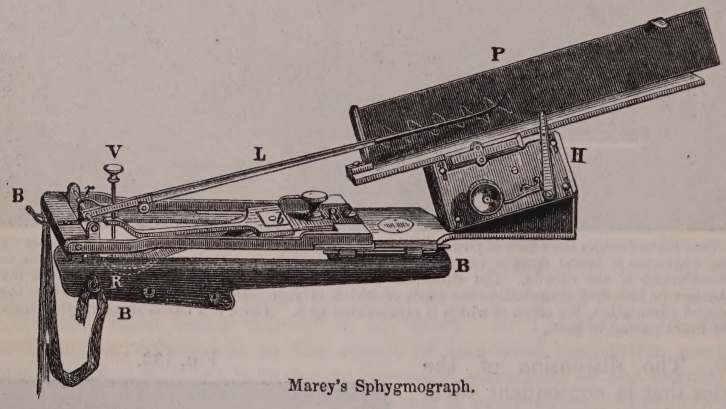
Fig. 133.



The dark line shows the period during which a powerful electrical stimulus was simultaneously applied to the sympathetic and to the chorda tympani nerve. It is seen that the sympathetic first responds to the stimulus as in Fig. 131, overcoming the chorda, but the chorda subsequently exerts its full action.

than the longitudinal; but these experiments were made under conditions so different from those of the living artery, that but little weight can be attached to them. It is to be remembered, however, that every increase in length augments the capacity in only a *simple* ratio; thus a tube of 21 inches in length will only contain *one-twentieth* more than a tube of 20 inches long, of the same diameter. On the other hand, every increase in diameter augments the capacity of the tube in the ratio of the *square* of that increase; thus the capacity of a tube of 21 lines in diameter will be to that of a tube of 20 lines, as 441 : 400, or *one-tenth* more. Consequently, supposing the increase of *capacity* to take place equally in both directions, the increase in longitudinal *dimension* will be far more apparent than the *transverse* enlargement. The total increase of capacity was estimated by Flourens, from experiments upon the carotid artery, at about 1-23rd part; but it is affirmed by Volkmann* that this must not be considered by any means a constant ratio, since it varies in different arteries, and in the same artery under different circumstances. It has also been attributed to *elongation* of the artery, which was supposed to be lifted from its bed at each pulsation, and, when previously straight, to become curved; the impression made upon the finger by such displacement, not being distinguishable from that which would result from the dilatation of the tube in diameter. A very obvious example of this upheaval is seen in the prominent temporal artery of an old person. The real cause of the sensation given by the pulse to the observer, however, may be considered to be the return of the artery to a cylindrical form under increased internal pressure, after it has been more or less flattened by the pressure of the finger against an unyielding structure, while in a comparatively flaccid condition.

Fig. 134.



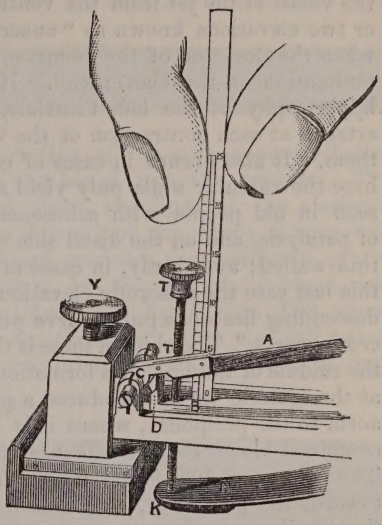
Marey's Sphygmograph.

The production of the pulse is a subject of much interest. The passage of a continuous current of fluid through an elastic tube takes place in accordance with the same laws as those which govern its passage through a rigid tube; but if into an already tightly-filled elastic tube which is closed at its extremity a jet of fluid be driven, the first part of the tube undergoes distension, and an oscillatory movement is impressed on the particles of the fluid, which rapidly propagates itself in the form of a positive wave to the extremity of the tube, and is then reflected to and fro along the tube till it dies out. In this case there is only an oscillation of the particles of the fluid, but no translation of

* Op. cit., chap. xiv.

them. If, however, the extremity of the tube be open, and a jet or succession of jets of fluid be forced into it whilst the fluid it contains is in motion, the result is a combination of undulatory movement with current movement. The velocity of the wave is proportional to the elasticity of the tube; it varies inversely with the density of the liquid; it diminishes gradually with the length of the tube, and it increases with the rapidity of impulsion of the fluid.* The amplitude of the wave is proportional to the quantity of fluid which penetrates into the tube and the briskness of the jet. It diminishes as the wave advances.† The fluctuations of the Pulse in the living body without exposure of the artery can be rendered apparent by the use of an instrument originally invented by Vierordt, but materially modified and improved by Marey, termed the Sphygmograph. The general arrangement of the instrument is shown in Fig. 134, where the part B B is applied to the forearm, whilst the pressure on the artery is effected by a very light steel spring, terminating in a small plate of ivory R, capable of elevation or depression by the screw V. The long arm of the wooden lever L terminates in a fine point touching the plate of smoked glass, or glazed card P, which is made to move gradually forwards by clockwork in the box H. The immediate descent of the lever after its elevation is accomplished by the very delicate spring at *r*. A modification of Marey's instrument is shown in Fig. 135, by which the pressure exerted on the artery can be approximatively measured. The tracings made by either of these instruments show that under ordinary circumstances the period of ascent or of increase in the tension of the arterial walls is rapid; whilst the period of decrease, during which the elasticity of the larger arteries is acting, is comparatively slow and prolonged.

Fig. 135.



This figure shows a modification of Marey's Sphygmograph, by means of which the amount of pressure exerted on the artery can be approximatively measured. A, registering lever; D, knife-edge on which it rests; K, spring placed over the artery; T, screw regulating the pressure, the amount of which is ascertained by the index B.

Fig. 136.

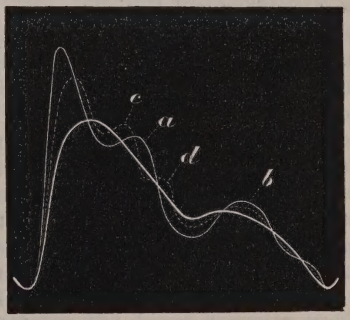


Diagram to illustrate the relation of the Sphygmographic tracing to the true pulse wave. The thick line represents the true pulse wave, the thin line the sphygmographic tracing, the dotted line the tracing drawn by a sphygmograph having a secondary spring to keep down the lever. *a*, first, or dicrotic wave; *b*, secondary wave; *c*, *d*, two small waves into which the tidal wave may be broken by the action of the secondary spring.

* Moens' ("Die Pulscurve, Leiden," 1878) experiments have shown that the rapidity of propagation of a pulse wave in an elastic tube is inversely as the square root of specific gravity of the fluid; that it is also in direct proportion to the thickness of the tube with the same lateral pressure; that it is inversely as the square root of the diameter of the tube with the same pressure; and, lastly, that it is as the square root of the coefficient of elasticity of the wall of the tube with the same pressure.

† See Marey, "La Methode Graphique," 1878, p. 352.

The ascending limb of a pulse-curve is usually steep and uniform; it represents the expansion of the elastic arterial wall consequent upon the entrance into the vessel of the jet from the ventricle. It sometimes, however, presents one or two elevations known as "anacrotic elevations." These occur in general when the duration of the incurrent jet is prolonged beyond the time of an undulation of the elastic wall. It occurs therefore in cases of dilatation and hypertrophy of the left ventricle, when a large jet of blood is driven into arteries at each contraction of the ventricles requiring a long time to distend them. It also occurs in cases of constriction or rigidity of the vessels, since here the vascular walls only yield slowly to the instreaming jet. It is hence seen in old people with atheromatous vessels, after a cold bath, in cases of paralysis, and on the distal side of a ligature when the collateral vessels are thin-walled; and, lastly, in cases of insufficiency of the semilunar valves. In this last case the anacrotic elevation is due to the auricular contraction. The descending limb of a pulse-curve presents two secondary elevations or "katacrotic waves." The chief of these is the "dicrotic" elevation, which occurs about the middle of the line. Its formation is thus explained by Landois:*—As soon as the systolic jet has produced a positive wave rapidly progressing from the aorta to the periphery, where it is lost, the vascular walls contract upon the contained blood, the first effect of which is the closure of the semilunar valves. The column of blood still continuing to be compressed on all sides, streams towards the periphery, but, meeting with resistance, passes back and tightens the semilunar valves to the uttermost, which gives rise to a second positive wave, which again distends the vessels in the direction from the aorta to the smallest arteries, where it is lost. This is the *dicrotic wave*. A third wave may arise in a similar manner, and pursue a similar course, but is only perceptible in the carotids or subclavians, being lost before it reaches the arteries of the lower limbs. It follows from the mode of production of the secondary and tertiary waves that they occur later in proportion to the distance of the artery from the heart. In the carotid, which is the nearest accessible artery to the heart, the dicrotic elevation occurs about 0·35 to 0·37 sec. after the commencement of the pulse. In the Radial, the apex of the dicrotic wave occurs from 0·36 to 0·40 sec. after, and in the dorsal artery of the foot 0·45–0·52–0·59 sec. after the beginning of the pulse, according to the height of the individual. The dicrotic wave becomes smaller and less marked in proportion to the distance of the artery from the heart. It is more distinctly marked in proportion as the systolic contraction is short and vigorous; and, lastly, the height of this wave is great in proportion as the arterial tension is small. Hence it becomes conspicuous during venesection, on exposure to heat, the standing position; whilst it is rendered indistinct by circumstances increasing arterial tension, such as exposure to cold, compression of large trunks, expiration and irritation of vaso-motor nerves.† The fulness of the pulse, or, in other words, the amplitude of the pulsation, is in inverse ratio to the tension of the walls of the vessel; whilst the hardness of the pulse is indicative of arterial tension, and may be produced either by the heart acting with great force and injecting more blood than the arteries can discharge through the capillaries, or by the contraction of the capillaries, themselves preventing the escape of the blood from the arteries into the veins. M. Marey has clearly shown how these two conditions of the arterial system may be induced by acting upon the capillaries alone, and either facilitating the passage of the blood through them, or, on the contrary, rendering it more difficult. Thus the tracing obtained by his

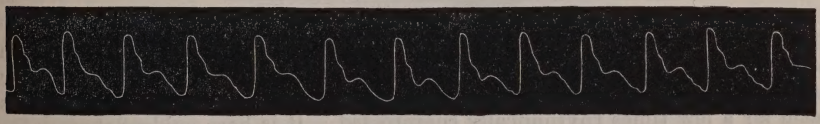
* Landois' "Physiologie," 1879, p. 137. † See Maragliano, "Centralblatt," 1876, p. 27.

Sphygmograph, after exposure to a cold bath of one minute's duration, is shown in Fig. 137. It is that of a hard pulse, in which there is considerable

Fig. 137.

tension of the arterial wall; for the contraction of the cutaneous capillaries constitutes an obstacle to the passage of the blood from the arteries. The line of ascent is accordingly sudden and short, the limit of the elasticity of the vessel being soon reached, and the summit of the curve is rounded; whilst the line of descent is protracted and gradual, the resiliency of the vessel being only capable of reacting slowly on the contained blood, and there is no tendency to dicrotism. On the other hand, Fig. 138 shows the effects of a hot-air bath, and presents the characters of a soft full pulse; a pulse of deficient tension, in which the greater boldness of the curves, their

Fig. 138.



sharper summits, and the marked tendency to dicrotism, may particularly be noticed; as well as the increased frequency of the heart's action, corresponding to the diminished exertion which it has to make in propelling the column of blood through the same vessels. The variations in the curves presented by Sphygmographic tracings have for ages been partially and imperfectly recognised by the *tactus eruditus*, and depend on the vigour and frequency of the heart's action; the fulness of the blood-vessels and degree of elasticity of their walls; and upon the state of relaxation or contraction of the smaller arteries. Thus, amongst others, may be mentioned:—

1. The large compressible pulse of fever, in which the rise and fall of the primary wave curve are sudden. The tidal wave is absent, the dicrotic wave large, and the blood-pressure low. Here the heart's action is vigorous, but the smaller arteries and capillaries are relaxed, allowing the blood injected into them to pass readily into the veins.

2. The large hard pulse of Bright's disease with contracted granular kidney. Here the heart's action is vigorous, but the smaller vessels are contracted, and their walls less elastic. Hence the blood-pressure is high, the tidal wave large, and distinctly separated with well-marked dicrotic, and even a third secondary wave (Galabin).

3. The small hard pulse of peritonitis due to less vigorous action of the heart, with coincident contraction of smaller arteries.

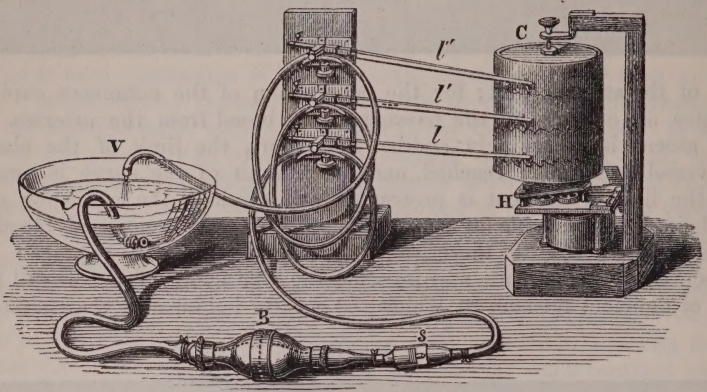
4. The small, soft, and thready pulse of collapse, in which the heart's action is feeble, and the vessels are relaxed with perhaps diminution of supply of blood.

5. The irregular and the intermittent pulse are conditions associated with disease of the heart and disordered cardiac innervation.

241. The mode in which the pulse is propagated through the arteries is made manifest by the following ingenious experiment devised by M. Marey:— A small caoutchouc bag (Fig. 139, B) is fitted with valves which permit the

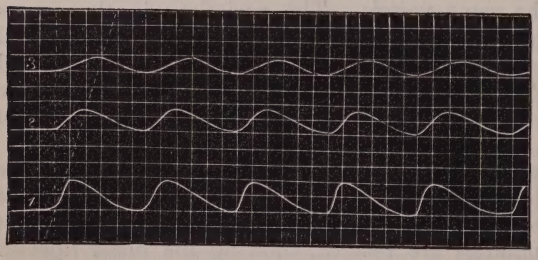
contained fluid to move only in one direction, and is connected with a long elastic tube forming a rude resemblance to the Heart and Arteries. At three different points of its length the tube is placed under the control of a Sphygmo-

Fig. 139.



graph, the levers of which, $l\ l'\ l''$, register their movements on the drum C in such a manner that their tracings may be exactly parallel and comparable with one another. Fig. 140 shows such a triple tracing after the india-rubber bag has been for a few times rhythmically compressed. It is here evident that, as indicated by the oblique dotted line, the period at which the maximum of tension is attained, is latest in that portion of the tube which is most distant from the impelling organ, and a certain, though minute, retardation occurs in the passage of the wave through the column of liquid. The actual amount of this retardation has been carefully investigated by Czermak,* with the aid of his photosphygmograph, in which the fluctuations of a ray of light reflected from a small mirror placed over the radial artery are registered on a screen of prepared photographic collodion. The mean of a series of twenty experiments showed that the pulse in the radial artery at the wrist was 0·18 sec. earlier than in the dorsal artery of the foot; whilst the shock of the heart, which is transmitted nearly instantaneously to all parts of the system, occurred 0·159 of a sec. earlier than the pulsation at the wrist, and 0·087 sec. earlier than the pulse in the carotid. It therefore takes about 1-6th of a second for the primary pulse wave to travel from the heart to the foot, and estimating this distance roughly at five feet, the rate of the pulse wave is about thirty feet a second, with which Weber's estimating (28·5 feet) closely agrees. The rate of the pulse wave is, of course, to be carefully distinguished from the velocity of the blood itself. Grunmach's experiments† show that in the healthy dog the rate of propagation of the pulse wave is 75 cm. in 0·158 sec. or 4·746 m. in one second

Fig. 140.



* "Mittheilungen aus dem Privat-Laboratorium," Heft 1, 1864, p. 27.
† "Archiv f. Anat. v. Physiol. His. and Braun.," 1879, p. 425.

(or about 15 feet). After paralysis of the peripheric vascular nerves by means of æther, chloral hydrate and morphin, the rate fell to 3·304 m. in one second, the blood pressure being coincidently reduced, and reduction to a still greater extent occurred after section of the spinal cord. On the contrary, when the blood pressure was increased by stimulation of the spinal cord, the rapidity of propagation of the pulse wave amounted to 6·25 m. in one second.

His experiments on man showed that the rapidity of propagation of the pulse wave was greater towards the lower extremity than along the arm, being, in one instance, 5·123 m. in one second along the arm and 6·620 m. towards the foot. It was smaller in children than in adults. As in the dog, circumstances that induced either local dilatation or local constriction of the lumina of the vessels caused retardation of the rate of propagation of the pulse wave. Again, in the above tracings it may be noticed that the force of the impulse, or the extent of the vertical movement of the lever, diminishes with increase of distance from the impelling organ, producing the effect which Poiseuille described as "extinction of the wave."

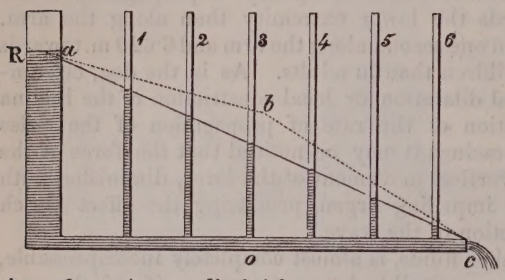
242. Since the blood, like other fluids, is almost completely incompressible, all force applied to it becomes perceptible by movement, or if this be prevented, by lateral pressure exerted against the sides of the vessels, and these two, the velocity of movement and the lateral pressure, however much each may vary in amount, always together represent the impelling force. The circumstances that chiefly affect the movement or velocity of the blood, independently of variations in the amount of the propelling force, are those which increase or diminish the friction between it and the vascular walls. Thus, it will be retarded by diminution of the diameter of the tubes, or, as was observed by Hunter, by curves, angles, or divisions in their course,* or by their rigidity,† or by increased viscidity of the blood itself; or, lastly, by augmentation, of its attraction for the tissues, or for the walls of the vessels through which it is coursing. These constitute the obstacles or resistance to the passage of the blood; and with their increase, if the impelling force remain the same, whilst the velocity of its movement is retarded, the amount of lateral pressure exerted is increased. The effects of diminished resistance in diminishing pressure may be understood from a consideration of Fig. 141. For here the height to which the fluid will rise in the small tubes numbered 1—6, is the expression of the pressure of the liquid against the walls of the tube R *o c* at different points. If the fluid were stationary, from the closure of the orifice *c*, it would, according to a well-known law, rise to the same height in all; but when a discharge is allowed to take place from *c*, a gradual diminution of pressure, indicated by the diagonal line R *c*, may be observed as the outlet is approached. Now, if the bore of the tube be contracted at any part, as at *o*, an obstacle to the discharge of the fluid will be created, through the increase of friction; the pressure against the walls of the preceding portion of the tube R to *o* will increase, and consequently the line of levels will rise in

* So Budge ("Physiologie," 1862, p. 309) found that a simple tube (*a*) would deliver more fluid in a given time than a bifid one (*b*), the sectional areas of whose arms were together equal to *a*, and the bifid tube more than a trifid one (*c*) in the proportion of (*a*) 3860 : (*b*) 3400 : (*c*) 3100, the pressure being equal in all three cases.

† Thus Marey has shown that whilst elastic and rigid tubes of equal diameters will discharge an equal quantity of fluid as long as the stream is continuous, the moment the stream becomes intermittent an advantage is gained by the elastic tubes, apparently owing to the diminution of friction in the latter, and the conversion of the jetting movement of the fluid into a more continuous, uniform, and steady flow; and herein, perhaps, we may perceive an explanation of the hypertrophy of the Heart, so frequently observed as a concomitant of a rigid aorta in old age. See "Annal. des Sci. Nat. Zool.," 1857, t. viii. p. 330; and Marey's "Thèse Inaugurale," 1859.

that part, as indicated by the dotted line R *b c*. If, on the other hand, the outlet be enlarged, the fluid will be discharged more easily, and the line of levels will fall with great rapidity. Upon these principles M. Marey* has constructed an apparatus bearing some resemblance to the different systems of vessels in the body, a constricted portion at *o* (Fig. 141) representing the capillaries,† and being preceded by a wider portion for the Arteries, and followed by a still wider one for the Veins. By this instrument it may be shown physically that the pressure is highest in the Arterial vessels, whilst it is much less in the Capillaries, and is lowest in the Veins.‡ It may also be shown that the mean tension of an Artery diminishes in proportion to its distance from the heart, and is by so much the less in proportion as the capillaries are dilated, and thus constitute a smaller obstacle to the passage of the arterial blood. These facts, at least as regards the difference of the pressure in the arterial and venous systems, were clearly perceived by Hales, and having been substantiated by Bernard with the differential Manometer, Fig. 142 ; the two mouthpieces of which, *e e*, being inserted into Arteries at the same distance from the heart, as the two carotids or the two crurals, the level of the mercury on the two sides remains equal, indicating equality of pressure; whilst if one be placed in a more distant Artery or into a Vein, the mercury constantly rises on that side, thus showing a diminution of pressure or tension. If the contracted or capillary portion of Marey's apparatus be enlarged, the fluid will pass through it with less resistance, and the pressure in the Arterial portion will diminish, and *vice versâ*. This has actually been observed by Bernard in the living subject: for on placing the mouthpieces of his differential Manometer into the two facial arteries of a horse, the mercury stood at the same level in each arm of the instrument; but on division of one of the cervical sympathetic nerves, the mercury instantly rose on that side, indicating a diminution in the tension of the vessel. Now it has been ascertained by M. Brown-Séquard that section of the sympathetic causes a dilatation of the Capillary vessels, and therefore facilitates the passage of the blood through them; and the counter-proof is shown by stimulating the cut extremity of the Sympathetic, which inducing contraction of the Capillaries, increases the resistance to the passage of the blood from the arteries, and augments the tension of their walls, as is indicated by the gradual falling of the mercury on the stimulated side, till the pressure there may even exceed that of the healthy one.

Fig. 141.



243. The absolute pressure of the blood in the living vessels has engaged the attention of many observers. Hales§ endeavoured to ascertain it by inserting long pipes into the vessels of living animals, and measuring the

* Brown-Séquard's "Journ. de la Physiol.," vol. ii. p. 436. See also Rutherford's 'New Scheme of the Circulation,' "Journ. of Anat. and Phys.," 1872, vol. vi. p. 249.

† The capillaries of the body, though in their aggregate sectional area much larger than the aorta, yet by reason of their smallness, and the consequent great increase of friction against their walls, operate virtually as such a constricted portion.

‡ In the living body the pressure rises again in the veins, as their collective calibre is much less than that of the capillaries, though greater than that of the arteries.

§ "Hæmastatics," vol. i. pp. 1–60.

height to which the blood rose. In a Mare, when the tube was introduced into the crural artery, it rose 8 ft. 3 in.; in two Horses, 9 ft. 8 in. and 9 ft. 6 in. From parallel experiments upon sheep, oxen, dogs, and other animals, and from the comparison of the calibre of their respective vessels with that of the human aorta, Hales concluded that the usual force of the heart in man would sustain a column of blood 7½ ft. high, the weight of which would be about 4 lbs. 6 ozs. on the square inch. Poiseuille, improving on Hales' method, employed a much more portable instrument in the form of a doubly-bent tube (Fig. 143), containing mercury in the curve, and a solution of carbonate of soda in the mouthpiece, which prevented the formation of clots. A still further improvement was made by Ludwig and Volkmann, by placing Poiseuille's instrument in connection with a revolving drum, on which tracings indicating the fluctuations of the pressure could be taken. The instrument so modified is called the "Kymographion," and is represented in Fig. 144. The tracing on page 321 gives a normal tracing of arterial pressure obtained with the mercurial Kymograph from a rabbit. Poiseuille estimated the pressure in the arteries at 6·3 inches of mercury on the square inch, which he assumed as the standard for all arteries, and for all Mammalia. But the tracings of Ludwig and Volkmann showed that the range of variation is very wide, being in the carotid of the Horse from 6–13 inches, in the Dog from 7–8 inches, and in the Rabbit from 2–3½ inches; in Man it is probably about equal in the larger arteries to a column of mercury 8 inches in height (Ranke, 6 or 7 Faivre). Bernard has invented a lighter instrument, termed the "Cardiometer," the indications given by which are somewhat higher than those obtained by Poiseuille's apparatus. The following table presents the results of Volkmann's observations† upon the relative lateral pressure at four points of the circulation in different animals, expressed in millimetres—namely,

Poiseuille's Hæmadynamometer.—A, mouthpiece.

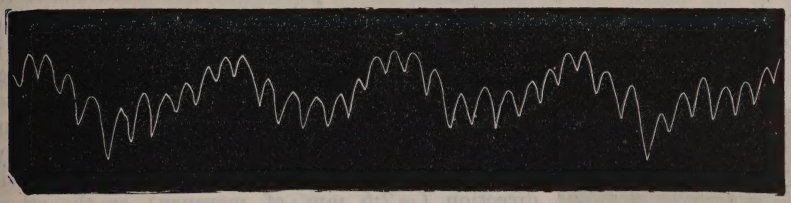
The periodic variations of the blood-pressure depend, on the one hand, upon the frequency and vigour of the contractions of the heart, and, upon the other hand, on the resistance the blood meets with in its passage through the smaller vessels. The pressure of the blood in the arteries rises with increased strength and frequency of the heart's action, since more blood is then pumped into them than can readily escape through the capillaries. Hence we find that section of the vagus which is followed by a quicker pulse, produces higher mean pressure, whilst stimulation of the vagus, which causes slowing of the pulse, is followed by a fall in the pressure. The pressure rises with any increase in the absolute amount of blood in the system, and falls with a decrease. Hence it increases after meals, and diminishes

Fig. 144.

First axis, which revolves once in a minute ; 2, second axis, which revolves once in ten seconds ; 3, axis, which revolves in 1½ seconds. The instrument is furnished with other cylinders suitable for the reception of bands of paper, the surface of which can be blackened after they are fixed on to the cylinders, by causing the cylinder to revolve over the flame of a petroleum lamp, though more frequently the tracings are taken with a brush wetted with solution of anilin dye.

after fasting. The pressure rises when, from any cause, the smaller vessels contract, since this must increase the resistance to the discharge of the blood from them;

Fig. 145.



and it falls when they dilate, because then the blood traverses them more easily. Hence it rises on exposure of the body to cold, which contracts the capillaries, and falls in a warm temperature, which leads to the dilatation of the capillaries, and this shows too that local variations in the contraction of the vessels influence the pressure of the blood in the rest of the system. Constriction of a particular artery causes diminished flow through the artery itself, increase of the pressure of the blood throughout the arterial system, and augmentation of the flow of blood through all the other arteries of the body; whilst dilatation of an artery has the opposite effect. Fick,* from experiments made on the dog with his modified spring manometer (Fig. 146), found the pressure in the right auricle nil (= atmospheric pressure); during inspiration it sank to 10 mm. of mercury below zero. In the right ventricle the pressure varied from 18–42 mm., and in the left ventricle the maximum was 140 mm. The pressure of the blood in the aorta rose as high during the period of systole as in the ventricle, but it did not fall so low during the diastole. Badoud,† working under Fick and using his C-spring manometer, found the pressure of the blood in the pulmonary artery constantly below 60 mm. of mercury; after section of the spinal cord it fell considerably, and when the cord was stimulated electrically it not only rose, as occurs in the systemic arteries, but rose considerably above the normal, this being due to the muscular contraction excited in the body generally. Worm Müller‡ has shown that when the tension of the vascular system has been lowered by section of the spinal

cord and cardiac nerves, the blood-pressure cannot again be raised to its normal height by the injection of blood into the vessels. He also showed that blood to the extent of two per cent. of the body weight can be withdrawn from the body without materially lowering the blood-pressure. The influence of the respiratory movements upon the pressure of the blood in the vessels is of much interest.* After an ordinary expiration the heart and large vessels in the chest are exposed to a pressure acting through the tissue of the lung, which, as Wündt has pointed out, is equal to the difference between the pressure of the air on the one hand (=750 mm. of mercury) and the elasticity of the lungs acting in the opposite direction (=7·5 mm. of mercury) on the other; whilst on the vessels outside the full pressure of the air is exerted. The blood cavities in the chest being thus exposed to less pressure than those of the rest of the body have a tendency to dilate until restrained by the elasticity of their walls. The venous current is affected to a greater degree than the arterial, since the walls of the veins are thinner and less elastic than those of the arteries. In ordinary inspiration the elasticity of the lungs rises to 9·5 mm. of mercury, and in extraordinary respiration it would even support a column amounting to 30 mm. of mercury in height, and the suction power of the cavities is correspondingly increased. In consequence of the descent of the diaphragm this is chiefly exerted upon the veins of the abdominal viscera. In expiration, on the contrary, the pressure on the thoracic vessels being increased, the escape of the blood by the arteries is facilitated, whilst there is a tendency to arrest the flow in the veins; the valves in the latter, however, offer an obstruction to a backward flow, even in extreme expiration, beyond certain limits. The general result of this is, that the pressure of the blood in the veins of the body at large, rises during expiration, and falls during inspiration. In the arterial tracing similar curves occur (complicated, of course, with those of the cardiac beats), but in the opposite direction, the ascending portion of the curve (corresponding to increase of pressure) occurring chiefly during the period of inspiration, the descending portion of the pressure-curve chiefly occurring during expiration. The rise of blood-pressure in the arteries during inspiration depends on the heart becoming filled with more blood from the veins at this period than during expiration, and hence acting more vigorously and at the same time more

frequently. But inasmuch as the filling of the cardiac cavities with blood does not take place at the commencement of inspiration, nor the diminished supply of blood to them with the commencement of expiration, and since, further, the dimi-

* See Zuntz, Pflüger's "Archiv," Band xvii. 1878, p. 374; also Funke and Latschenberger, idem., p. 547.

nution of pressure within the thoracic cavity in expiration exerts a suctional power upon the contents of the arteries, whilst the increase of pressure during expiration tends to drive out the blood, it comes to pass, as was shown by Einbrodt,* that the respiratory phases represented by the dotted line in the accompanying figure (Fig. 148) do not exactly correspond with the variations of pressure, but that the pressure continues to fall for a little while after the commencement of inspiration, and continues to rise for a little while after the commencement of expiration. Curves essentially similar to those observed in normal respiration are seen when the animal is poisoned by curare, if artificial respiration be maintained. On suspending the artificial respiration the mean pressure rises, and curves (Traube's curves) then begin to appear, which gradually become more and more marked, and are synchronous with the suppressed respirations; they are probably partly dependent on the relation of the gases in the blood to the vaso-motor centre, and partly to the direct action of the imperfectly arterialized blood upon the local nerve centres of the vessels themselves.

244. *The rate of movement* of the blood in any artery can only be guessed at as regards the human subject from the comparative results of experiments upon the lower animals; but several methods have been suggested, by which it may be ascertained in them with some approximation to truth. One of

Fig. 149.

these, employed by Volkmann, and termed by him the Hæmodromometer, is exhibited in Fig. 149, where A shows the instrument as it is inserted between the two cut extremities of an artery or vein. In this position the blood continues to flow in the original direction; but by a simple mechanical arrange-

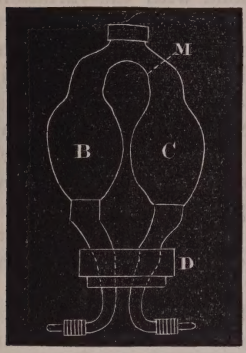
ment its course can be suddenly diverted (as in B), through the bent tube filled with serum in the direction of the arrows. The rapidity of the current may be readily estimated by timing its course along the scale at the side.

Fig. 150.



Ludwig's Stromuhr.

Ludwig has suggested an instrument which he has named a "Stromuhr," or current measurer, the principle of which is represented in Fig. 150. This consists of an arched glass vessel with two legs, of which B and C are considerably dilated, and the extremities of which are inserted into the vessels; that directed towards the heart, C, being filled with pure olive oil, whilst the other directed towards the capillaries is filled with defibrinated blood. If the capacity of the limb C up to the point M be known, and the time occupied in filling it be noted, it is easy to calculate the quantity of blood passing through the artery in a given period. At D is a mechanical arrangement by which the current of blood through the two limbs may be reversed, and the experiment repeated on the same animal. A third instrument, adapted for measuring the rapidity of the blood-current is that represented in Fig. 151, devised by Vierordt, and termed by him the "Hæmatochometer." This consists of a small glass cell filled with water, with two mouthpieces for insertion into the vessel, and a light vertically-suspended, and easily-movable pendulum, placed close to the point of entrance of the current from the upper extremity of the divided artery. The amount of deviation from the perpendicular produced by the instreaming blood on the pendulum, as measured by the scale, indicates the velocity of the current. Volkmann gave the rapidity of the stream in the carotid of the Horse at from 12–17 inches per second, and in the Dog at about 12 inches per second. In the crural artery of the Dog it had fallen to $6\frac{1}{2}$ inches, and in the metatarsal of the Horse to $2\frac{1}{4}$ inches per second. Vierordt estimated it at $10\frac{1}{2}$ inches per second in the carotid of Man,* and at $2\frac{1}{4}$ inches per second in the metatarsal artery. Chauveau,† with a similar but somewhat improved instrument, estimated the rapidity of the blood in the carotid of the horse at 20·28 inches per second during the systole of the heart, falling to 8·78 inches during the diastole. Volkmann found the rapidity of the current in the jugular vein of the dog to be 9 inches per second, and Ludwig and Dogiel‡ found it to vary in the carotid of the rabbit from 4 inches to 9 inches, and in the carotid of the dog from 14 to nearly 30 inches in the second. Cyon and Steinmann found that great diminution in the rapidity of the flow of blood followed section of the spinal cord, which was clearly due to the consequent paralysis of the vaso-motor nerves, and the accumulation of blood in the veins of the viscera. The instrument adopted by M. Lortet§

§ "Recherches sur la Vitesse du Cours du Sang," &c., Paris, 1868.

(Fig. 152) is founded on the same principle as the one suggested by MM. Chauveau, Bertolus, and Laroyenne.* It consists of a short tube, open at both ends (*a*), which is introduced into the artery. On one side, near the middle, is a square opening (*b*), which is closed by a plate of caoutchouc. The caoutchouc is pierced by a long and light lever (*c*), the short and somewhat broader end of which hangs in the current of blood, whilst the long end records its corresponding but opposite movements on a rotating drum, the fulcrum being the point where the lever is gripped by the sides of the opening in the india-rubber. Connected with the instrument is a sphygmoscope and a sphygmographic apparatus, with the object of obtaining traces of the pulsations, the tube of the former being soldered, on the one hand, into the side of the primary or hæmodromographic tube, and, on the other, being connected with an elastic cushion filled with air and supporting a lever the movements of which are registered just below those of the lever indicating the rapidity of the movement of the blood. Fig. 153 shows a double normal tracing obtained from the carotid of a horse with a pulse of 40 per minute. Each complete trace, therefore, occupied a second and a half. From this it will be seen that the increase of the rapidity commences briskly, the line of ascent being sharp, and reaching its acme in the space of two-tenths of a second. In the following tenth the line rapidly falls. In the fourth and fifth tenths the rapidity diminishes insensibly, and in the sixth the line is almost horizontal, though still above the zero line. At the seventh-tenth second is a slight elevation, showing a dicrotism of rapidity. During the succeeding eight-tenths of a second the line, though descending, presents undulations corresponding to oscillations of the rapidity. Amongst the more important results of his observations, M. Lortet believes he has shown that the blood attains its maximum of rapidity shortly before the systole of the heart, as indicated by the pressure in the arteries, reaches its greatest intensity. The closure of the sigmoid valves exerts little influence on the rapidity. The rapidity is greatest during expiration, and least during inspiration. Section of the spinal cord in the atlo-occipital region, or of the Pneumogastrics, increases both the speed of the blood and the pressure in the arteries. On ligature of one carotid the rapidity of the blood was found to increase in the other.

4. *Movement of the Blood in the Capillaries.*

245. In Man, as in all the higher Animals—in the adult condition at least—the Capillary circulation is almost entirely carried on through tubes having distinct membranous parietes, the only known exceptions being in the case of the spleen and the maternal part of the placenta (§ 157, II.)* These tubes commonly form a minutely-anastomosing network (Fig. 154), into which the blood is brought by the ramifications of the arteries on one side, and from which it is returned by the radicles of the veins on the other. The length of an ordinary capillary is about 1-50th to 1-25th of an inch. The walls of the larger tubes are composed of a delicate membrane, on the inner surface of which is a single layer of epithelial cells possessing nuclei, and of fusiform shape, in this respect resembling the cells lining the smaller arteries, but differing from those in the interior of the veins, which are lozenge-shaped, with wavy outline (Fig. 155). The walls of the very finest capillaries, as those of the retina and brain, are composed of a single layer of nucleated cell plates intimately united by an albuminous interstitial cell substance which is readily stained with nitrate of silver. The several cells are elongated, have pointed extremities, and are smooth or sinuous in contour (Fig. 155). They contain an intra-nuclear plexus of fibrils (Klein), and an oval flat nucleus. When the emigration of white corpuscles or diapedesis of red corpuscles is taking place, the corpuscles make their way through the cement substance, and this occurs especially in inflammation, when the capillaries are greatly distended. Minute openings or stigmata then appear which may enlarge till they form stomata. The capillaries in certain regions,† as the central parts of the nervous system and the mesentery, appear to be surrounded by a sheath between which and their own proper coat, lymph corpuscles have been observed; these spaces have consequently been regarded as extensions of the lymphatic system. Frey remarks, however, that it is not every adventitial tissue of a blood-vessel containing lymphoid cells that must be regarded as a lymph sheath. A circumstance that may frequently give rise to the deceptive appearance of such a sheath is that a blood-vessel is often bounded on each side by lymphatic canals, and this is most commonly seen in uninjected preparations. Without any basement membrane, this last only becoming perceptible in those of larger

Fig. 154.

* The capillary circulation may be well seen in the web of the foot, in the lung, mesentery, and tongue of the frog, the tail of tadpoles and of fish (see Caton, "Quart. Journ. of Mic. Science," 1870, p. 236), and in the peritoneum of mammals by the plan suggested by Stricker and Burdon-Sanderson, in which a guinea-pig is chloralized, the abdominal cavity opened, and the omentum floated in a warm bath containing common salt in solution. (See "Quart. Journ. of Mic. Science," Oct. 1870.)

diameter.* Non-medullated nerve-fibres have been traced by Beale to the capillaries, and by the aid of the gold method of staining, Klein has followed still finer fibres into the substance of the capillary wall.† The diameter of the capillaries varies in different parts of the body; those of the brain and lung being smaller than those of the liver or of bone. It also differs in different animals, in accordance with that of their blood-corpuscles; thus, the capillaries of the frog are, of course, much larger than those of Man. The ordinary diameter of the latter appears, from the measurements of Weber, Müller, and others, to vary from about the 1-300th to the 1-2500th of an inch; the extremes, however, are stated by Kölliker at as little as 1-5600th and as much as 1-1870th of an inch. As the diameter of the human capillaries, however, can only be examined after death, it is probable that these statements may not be altogether correct, particularly as tubes of the smallest of the above sizes would not admit ordinary blood-corpuscles. The dimensions of the individual vessels, indeed, are by no means constant; as may be seen by watching the circulation in any transparent part, for some little time. Putting aside those general changes in diameter which result from circumstances affecting all the capillaries of a part, it may be observed that a single capillary will sometimes enlarge or diminish by itself, without any obvious cause. Thus, the stream of blood will sometimes be seen to run into passages which were not before perceived; and it has hence been supposed that they were new excavations, formed by the retreating or removal of the solid tissue through which it passes. But a more attentive examination shows that such passages are real capillaries, which did not at the time of the first observation admit the stream of blood-corpuscles, in consequence of their small calibre, or of some other local impediment; and that they are brought into view by the simple increase in their diameter. The compression of one of the small arteries will generally occasion an oscillation of the corpuscles of blood in the smallest capillaries, which will be followed by the disappearance of some of them; but when the obstruction is removed, the blood soon regains its previous velocity and force, and flows into exactly the same passages as before. The capillaries of the red muscles of rabbits exhibit dilatations or small aneurismal enlargements, which may be regarded as constituting reservoirs

or storehouses of oxygenated blood for the supply of the muscles during their contraction.* It is still doubtful whether the capillaries possess any contractile power of their own, or merely vary in size owing to the elasticity of their walls, with the quantity of blood they contain.†

246. The opinion was long entertained that there are vessels adapted to supply the white or colourless tissues; carrying from the arteries the 'liquor sanguinis,' and leaving the corpuscles behind, through inability to receive them. Very well-marked examples of such non-vascular tissues are found in the cornea and hyaloid humour of the eye, and in the mucous tissue constituting the greater part of the umbilical cord. A considerable development was given to this view by the investigations of Virchow‡ and others; by whom it was attempted to be shown that in the various structures included under the term connective tissues, the corpuscles, which are almost constantly found disseminated through them, are to be regarded, like the lacunæ of bone, as centres and storehouses of nutriment, which is again distributed by their caudate prolongations (frequently assuming the form of elastic tissue) to the most distant parts. The idea that Nutrition can *only* be carried-on by means of Capillary vessels is, however, entirely gratuitous; for there is no essential difference between the nutrition of the non-vascular tissues, and that of the islets in the midst of the network of capillary vessels which traverse the most vascular. In both cases, the nutrient materials conveyed by the blood are absorbed by the cells or other elementary parts of the tissue immediately adjoining the vessels, and are imparted by them to others which are further removed; and the only difference lies in the amount of the portion of tissue which has to be thus traversed, so that we are only required to extend our ideas, from the largest of the islets which we find in the vascular tissues, to the still more isolated structures of which the non-vascular tissues are composed.—The disposition of the Capillaries, both as to the degree of minuteness and the plan of the reticulation which they form, varies so greatly in the different vascular tissues that it is possible to state with tolerable certainty the nature of the part from which any specimen has been detached,—whether a portion of Skin (Fig. 156), Mucous membrane (Fig. 157), Serous membrane, Muscles (Fig. 158), Nerve, Fat (159), Areolar tissue, Gland, &c. The degree of minuteness is obviously in accordance with the copiousness of the supply of blood which is required for the purposes of its circulation through the part; thus, the plexus is closest, where some change is to be effected in the blood itself, as in the absorbent, respiratory, and secreting organs; whilst it is widest in those parts which receive the blood solely for their own nutrition,—the nervous centres and muscles having a more minute reticulation than is seen in the generality of the last-named parts, in virtue of the peculiar activity of the molecular changes which take place in them. But the arrangement of vessels peculiar to each, evidently has reference only to the convenience of the distribution of blood among the elementary parts of the tissue, and varies with their form. It is not possible to imagine that it has any other relation than this to their functions; since the function of each separate element of the organ, of which that of the entire organ is the aggregate, is due to its own inherent vital

* Ranvier, "Archiv. de Physiologie," 1874, t. i. Peremeschkow, however, has observed similar enlargements in the capillaries of the ligamentum nuchæ of the dog and cat. Carus' "Zoolog. Anzeiger," 1878, p. 200.

† See Eberth, op. cit., and Stricker, "Wien. Sitz.-berichte," Band li. and liii. for arguments in favour of the former view, which are vigorously contested by Beale, op. cit., and Vulpian, "Leçons sur l'Appareil Vaso-moteur," 1875, p. 73.

247. The average *rate of movement* of the blood through the Capillary system may be determined with tolerable precision by microscopic measurement; and the observations of Hales, Valentin, and Weber concur in representing it to average in the systemic capillaries of the Frog 1·2 inch per minute.* In warm-blooded animals, however, the capillary circulation is probably much more rapid than this; the observations of Volkmann upon the mesenteric arteries of the Dog making its rate about 1·8 inch per minute; whilst Ludwig and Vierordt, from observations on the movement of the blood-corpuscles in the retinal capillaries of their own eyes, estimate the rapidity at from one inch in 41 seconds to one inch in 28 seconds. The layer which is in immediate proximity to the wall of the vessels flows from 9 to 17 times more slowly if the movement of the white corpuscles is to be taken as a means of estimating it (Weber). Assuming ·03 inch per second, however, as the rate, and comparing this with the rate of movement of the blood in the larger arteries, which seems on the average to be 11·8 inches per second, it is calculated by Volkmann that the aggregate area of the capillaries (being in an inverse ratio to the rate of the blood's movement through them) must be nearly *four hundred* times that of the arterial trunks which supply them.† Donders, on similar data, estimates it at 500 times greater, and Vierordt at from 800 to 850 times.‡ In regard to the pressure of the blood in the capil-

* Mosso, "Jahresber," 1874, vol. ii. p. 46; and Haro, idem., 1876, vol. ii. p. 79; Ewald, "Archiv f. Anat. u. Phys.," 1877, p. 208. The time occupied in the passage, or, as it is termed, the "transpiration-period" of the blood of the dog, through capillary tubes as compared to water taken as unity is 0·27, whilst human blood flows more rapidly, the proportion being 1 : 0·41. It runs more slowly as the temperature increases, and it also increases with increased specific gravity of the blood. The addition of carbonic acid gas, nicotin, chloral, ether, and small quantities of glycocholate of soda, retarded the passage; freezing and thawing again augmented it. See also Matthews Duncan and A. Gamgee, "Journ. of Anat. and Physiol.," vol. v. 1871, p. 150.

laries, Kries* finds the average amount in those of the tips of the fingers equal to a column of 37·7 mm. of mercury or 513 mm. of water.

248. That the movement of the blood through the Capillary system of vessels is mainly dependent upon the force which it derives from the Heart and from the coats of the Arteries, is a matter altogether beyond dispute. When the flow of blood through the capillaries of a transparent part, such as the web of a Frog's foot, is observed with the microscope, it appears at first to take place with great evenness and regularity. But on watching the movement for some time, various changes may be observed, which cannot be attributed to the heart's influence, and which show that a certain regulating or distributive power exists in the walls of the capillaries, or in the tissues which they traverse. Some of these changes, involving variations in the *size* of the capillary tubes, have been already referred to (§ 245), Others, however, are manifested in great and sudden alterations in the velocity of the current, which cause a marked difference in the rates of the movement of the blood through the several parts of the area under observation. Sometimes this variation extends even to the entire reversal, for a time, of the direction of the movement, in certain of the transverse or communicating branches; the flow always taking place, of course, from the stronger towards the weaker current. Not unfrequently an entire stagnation of the current in some particular tube precedes this reversal of its direction. Irregularities of this kind, however, are more frequent when the heart's action is partly interrupted; as it usually is by the pressure to which the tadpole or other animal must be subjected, in order to allow microscopic observations to be made upon its circulation. Under such circumstances, the varieties in the capillary circulation, induced by causes purely local, become very conspicuous; for when the whole current is nearly stagnated, and a fresh impulse from the heart renews it, the movement is not by any means uniform (as it might have been expected to be) through the whole plexus supplied by one arterial trunk, but is much greater in some of the tubes than it is in others; the variation being in no degree connected with their size, and being very different at short intervals.

249. Cases are of no very unfrequent occurrence in which the heart is absent during the whole of embryonic life, and yet the greater part of the organs are well developed. In most or all of these cases, it is true, a perfect twin fœtus exists, of which the placenta is in some degree united with that of the imperfect one; and it has been customary to attribute the circulation in the latter to the influence of the heart of the former, propagated through the placental vessels. This supposition had not been disproved (however improbable it might seem), until a case of this kind occurred, which was submitted to the most careful examination by an accomplished anatomist;† when the decisive result was obtained, that it seemed impossible for the heart of the twin fœtus to have occasioned the movement of blood in the imperfect one, and that some cause present in the latter must have been sufficient for the propulsion of blood through its vessels. It was a very curious anomaly in this case, that the usual functions of the arteries and veins must have been reversed; for the Vena Cava, receiving its blood from the umbilical vein nearly as usual, had no communication with the Arterial system (the Heart being absent), except

* Ludwig's "Arbeiten," 1875, p. 69, and "Uber. den Druck in den Blut-Capillaren der Menschlichen Haut." in the "Ber. de Konig. Sachs. Ges. d. Wiss. zu Leipzig," vol. i. 1875, p. 149.

† See Dr. Houston in the "Dublin Medical Journal," 1837.—An attempt was made by Dr. M. Hall ("Edinb. Monthly Journal," 1843) to disprove Dr. Houston's inferences; but a most satisfactory reply was given by Dr. Houston, at the meeting of the British Association, August, 1843, and published in the "Dublin Journal," Jan. 1844. See also "Edin. Med. and Surg. Journ.," July, 1844.

hrough the systemic capillaries; to which, therefore, the blood must have ext proceeded, returning to the placenta by the umbilical artery. This view f the course of the blood was confirmed by the fact that the veins were every- where destitute of valves.—It is evident that a single case of this kind, if nequivocally demonstrated, furnishes all the proof that can be needed of the xistence, even in the highest animals, of a 'propulsive power' resident in the essels; which, though usually subordinate to the Heart's action, is sufficiently trong to maintain the circulation by itself, when the power of the central organ s diminished. In this, as in many other cases, we may observe a remarkable apability in the living system of adapting itself to exigencies. In the acardiac Fœtus, the muscles of the vessels supply the place of the heart, up to the period of birth; after which, of course, the circulation ceases, for want of due aëration of the blood.

250. *Emigration of White Corpuscles and Diapedesis of the Red.*—One of the most frequent results of the inflammatory process is the formation of Pus, a serous or albuminous fluid holding a large number of corpuscles in suspension, the origin of which has been the object of much recent investigation. The cells are spherical, about the size of the white corpuscles of the blood, with softly-shaded contours and numerous granules in their interior. They contain one, two, or more nuclei. By Virchow* they were considered to be derived essentially from the proliferation of epithelial cells, and of connective-tissue corpuscles, and there can be no doubt that all intermediate stages between healthy epithelial cells and connective-tissue corpuscles, and pus-corpuscles, may be traced in inflammation, but numerous observers have noticed that under certain altered physical conditions of the circulation, an escape, both of the white and of the red corpuscles, takes place from the interior of the vessels into the adjoining tissues. This phenomenon was first observed in 1843, by Dr. W. Addison,† and was noticed to occur in inflammation by Waller,‡ who in a remarkable manner fully corroborated Addison's observation, declaring that he had seen the corpuscles protruding half-out of the vessels; whilst Addison had already arrived at the conclusion that pus-corpuscles of all kinds were only altered colourless blood-corpuscles. These statements, however, received little attention till the publication by Cohnheim§ of an essay on inflammation, in which he described the process of the passage both of the white and red corpuscles through the walls of the capillaries, and even of tolerably thick-walled veins, in detail.‖ The passage of the white corpuscles through the walls of the vessels appears to be due to some physical alteration in the walls of the vessel, reducing their tenacity, and permitting the colloidal substance of the corpuscles to penetrate them in a mode essentially similar, as Norris showed, to that by which a solid body may be made to traverse the thin film of a soap-bubble. This process is probably aided by the amœboid

‖ Cohnheim's observations immediately attracted great attention, and though they have been opposed by Feltz, Robin's "Journ. de l'Anatomie," 7me Année, 1870–71, pp. 33 and 505; Picot, idem., p. 465, and a few others, they have received the support of so many good observers, as of Stricker, idem., No. 6, 1867; Prussak, "Sitzungsber. d. Wien. Akad.," Band lxvi. p. 13; Caton, "Journal of Anatomy and Physiology," 1871, vol. v. p. 35; Norris, "Proceed. Roy. Society," 1871, No. 129; Bastian, "Transactions of Pathological Society," 1868, vol. xix. p. 461; and Heller, "Centralblatt f. d. Med. Wiss.," 1870, p. 310; that the main fact of the escape of the corpuscles from the vessels may be regarded as incontrovertible. In a recent essay, Cohnheim, "Neue Untersuchungen über Entzundung," Berlin, 1873, has given his latest views upon the point.

movements of the white corpuscles, and in part also by the increased pressure of the blood.* That neither the increased pressure of the blood, nor the mere dilatation of the vessels are sufficient *per se* to lead to the emigration of the corpuscles, seems to be demonstrated by the fact that if any slight injury, as a pinch of moderate severity, be inflicted on a transparent structure, as the tongue of a frog, the vessels in the vicinity may be seen immediately to enlarge (the arteries being first affected), permitting a more rapid current to flow through them. The veins then enlarge, and afterwards the capillaries. This condition is maintained for some minutes, when the arteries begin to contract, and with the capillaries return to their normal condition. The veins, however, do not follow this process of contraction, and hence the blood-current in them becomes slower. As soon as this stage is reached—viz., dilated veins with retarded circulation, a very abundant adhesion of colourless blood-corpuscles to the walls of those veins is seen to take place sooner or later; however, if the injury has not been too severe, the veins commence also to contract, in consequence of which the blood-current becomes quicker, and at the same time the number of adherent colourless corpuscles diminishes, until finally the normal condition is re-established. Now, notwithstanding there have been temporarily present the condition of dilated veins, slower blood-current, and marked adhesion of colourless blood-corpuscles to the wall of the veins, as well as increased pressure in the capillaries during the dilatation of the arteries, no coloured or colourless corpuscles will be seen to pass through the walls of the vessels; on the other hand, by proceedings adapted to produce physical changes in the relations of the walls of the vessels to the blood, an abundant emigration of the white corpuscles can be produced almost at will. Thus, Stricker and Prussak have both shown, that after the subcutaneous injection of a small quantity of a ten per-cent. solution of common salt, under the skin of frogs and rabbits, a condition of the vessels is produced in which the red corpuscles readily escape from the vessels; the same occurs when the main vein of a limb is tied; and these observers regard the diapedesis of the red corpuscles as the result of some "active condition" of the *capillary wall*, a view that Cohnheim also adopts, whilst Bastian attributes it to an "active condition," that is to say, to amœboid movements of the *red* blood corpuscles themselves. The emigration of the white corpuscles may also be readily witnessed in the mesentery of a frog inflamed by mere exposure to air; under such circumstances the white corpuscles accumulate, apply themselves to the sides of the vessels, where they either remain stationary or slowly oscillate. In a little while small colourless projections are seen on the outer surface of the vascular coat. These subsequently become pyriform, and ultimately detach themselves from the vessels, appearing as colourless contractile amœboid corpuscles, with one or several nuclei; the whole process being accomplished in from one to two hours.† That the presence of white corpuscles in large numbers in the tissues is not sufficient to constitute suppuration is shown well in the remarkable experiments of Tarchanoff‡ upon the effects of curare. On placing frogs under the influence of this poison, he found that the number of white corpuscles in the blood underwent great diminution, whilst the propor-

* It is possible, as Purves ("Centralblatt f. d. Med. Wiss.," 1874, p. 654), Arnold (Virchow's "Archiv," 1873, Band lviii. 203), Thomas ("Centralblatt," 1874, p. 364), and some writers maintain, that pores, which they believe are naturally present between the epithelial cells of which the walls of the smaller vessels are composed may enlarge, but this requires further confirmation.

† See Cornil and Ranvier, "Manuel d'Histologie Pathologique."

‡ Tarchanoff, "Archives de Physiologie," 1875, p. 33. See also Drozdoff, "Journal de la Méd. Milit.," 1872.

ion of the red increased.* The white corpuscles were found to be accumulated in the tissues and in the lymphatic vessels and sacs, which last were distended with lymph. These effects, which must be admitted to modify the statements of Goltz (see § 155), M. Tarchanoff attributes to augmentation of blood-pressure, owing to paralysis of the vaso-motor nerves, leading to dilatation and freer current of blood through the smaller arteries, and to repose of the muscles, and arrest of the contractions of the lymphatic hearts; yet, notwithstanding the exodus of the white corpuscles, no suppuration resulted, and on the animals recovering from the effects of the curare, the white corpuscles quickly disappeared from the tissues, whilst the lymph sacs returned to their normal condition.†

5. *Movement of the Blood in the Veins.*

251. The Venous system takes its origin in the small trunks that are formed by the re-union of the Capillaries; and it returns the blood from these to the Heart. The structure of the Veins is essentially the same as that of the Arteries; but the fibrous tissue of which their middle coat is made up bears more resemblance to the areolar tissue of the skin, than it does to the true elastic tissue, and presents the distinguishing feature of laminæ running longitudinally as well as transversely; and the muscular fibre-cells are usually much fewer in number, and are sometimes wanting altogether,‡ as in the veins of the uterine portion of the placenta; the veins of the cerebral substance and pia mater; the sinuses of the dura mater; Breschet's veins of the bones; the venous channels of the corpora cavernosa in the male and female; and probably the venous channels of the spleen, all of which are unprovided with muscular structure. Minute capillaries ramify in their outer coats. The *elasticity* of the Veins is shown by the jet of blood which at first spouts out in ordinary venesection, when, by means of the ligature, a distension has been occasioned in the tubes below it. Though the walls of the veins are thinner, they yet resist pressure better than the arteries. In an experiment of Wintringham§ the Aorta burst when the pressure rose to 158 lbs., whilst the Vena Cava only gave way when it reached 176 lbs. A slight *contractility* on the application of stimuli, and on irritation of the sympathetic nervous fibres, has been observed; but this is not so decided as in the arteries. The whole capacity of the venous system is considerably greater than that of the arterial; the former is usually estimated to contain from two to three times as much blood as the latter, in the ordinary condition of the circulation; and when we consider the great proportion which the veins in almost every part of the body bear to the arteries, we shall scarcely regard even the larger of these ratios as exaggerated. Of course the rapidity of the movement of the blood in the two systems will bear an inverse ratio to their respective capacities; thus if, in a given length, the veins contain three times as much

* The proportion of red to white in a cubic millimetre in a healthy frog was as 200,375 : 10,412; in a curarized frog it was 514,436 : 6,759 in the same quantity.

† Tarchanoff's experiments are, as he himself points out, in accord with previous observations of Paschutin, to the effect that curare causes an augmentation of lymph (Ludwig's "Arbeiten," 1872, p. 197), of Genersich, that muscular movements favour the flow of the lymph through the lymphatics, of Ranvier ("Comptes Rendus," 20th Dec. 1869), and Emminghaus (Ludwig's "Arbeiten," 1874), that section of the nerves of a limb increases the flow of lymph, and, lastly, of Hammarsten (Ludwig's "Arbeiten," 1872), that dogs from which much lymph has been withdrawn contain a larger amount of oxygen in their blood.

§ "Experimental Inquiry," &c., 1740.

blood as the arteries, the fluid will move with only one-third of the velocity. In the jugular vein its rapidity is about eight inches per second. Speaking generally, circumstances causing diminution of blood-pressure by dilatation of the arterioles, as division of the spinal cord, render the blood-current slower in the Veins.* Even at their origins in the capillary plexus, the Veins are larger than the Arteries which terminate in the same plexus; so that wherever the arterial and venous networks form distinct strata, they are readily distinguished from each other. The Veins are remarkable for the number of *valves* which they contain, formed of duplicatures of the endothelium, between the component laminæ of which connective-tissue fibres are interposed; and also for the dilatations behind these, which, when distended, give them a varicose appearance. The valves are single in the small veins, the free edge of the flap closing against the opposite wall of the vein; in the larger trunks they are double; and in a few instances they are composed of three flaps. The object of these valves is evidently to prevent the reflux of blood; and we shall presently see that they are of important use in assisting in the maintenance of the venous circulation. They are most numerous in those veins liable to be compressed by surrounding muscles, and they are not found in the veins of the lungs, of the abdominal viscera, or of the brain, or in veins measuring less than one-eighth of an inch in diameter. In the veins near the heart, like the innominate, jugular, and subclavian veins, a very well-marked *venous pulse* may be observed, due to the regurgitation of the blood into these vessels during the systole of the heart. The venous pulse wave is propagated from below upwards, and with a speed which is proportionate to the tension of the vascular walls. The curves of the tracing are, of course, greatly exaggerated in cases of insufficiency of the tricuspid valves.

Fig. 160.

Tracing of the pulse of the jugular vein in a healthy adult.—*a*, *b*, contraction of right auricle; *b*, *c*, contraction of right ventricle; *c*, closure of aortic valve; *d*, closure of valves of pulmonary artery; *e*, *f*, diastole of the right ventricle.

252. The *pressure of the blood* in the veins varies not only in different veins but in the same vein at different periods. In the veins near the heart a negative pressure is shown when a manometer is introduced into them, amounting to 0·1 mm. of mercury in the case of the vena innominata, the right subclavian, and left jugular vein. This indicates that a suction power is exerted on the blood, which is essentially attributable to the respiratory movements of the chest, though in part also due to the dilatation of the heart; and is of importance, since it permits the entrance of the fluid contained in the lymphatic duct into the general circulation, which would otherwise, considering the low pressure under which the lymph moves, be impossible. In the veins more remote from the heart, the pressure, instead of being negative, becomes positive, amounting to 3 mm. of mercury in the external facial vein; 4·1 mm. in the brachial; 5·2 mm. in the internal facial; 9 mm. in a branch of the brachial; and 11·4 mm. (or about half an inch) in the crural vein.† The influence of the respiratory movements on the pressure of the blood in the veins is evident from the occurrence of the respiratory pulse long ago described by Haller, which may be seen in the veins of the neck and shoulder in thin persons and in those especially who are suffering from pulmonary disease. During inspiration the veins are seen to be partially emptied, owing to the descent of their contents into the chest in order to supply the vacuum

* In regard to this point see Cyon and Steinmann, "Bulletin de l'Acad. des Sciences de St. Pétersbourg," t. xvi. 1871, p. 266.

† See Jacobson and Recklinghausen, Virchow's "Archiv," Band xxxvi. p. 1.

which is created at the moment of the contraction of the diaphragm; whilst during expiration the veins become turgid in consequence of the check in front and the accumulation from behind. The complete collapse of the larger veins during inspiration is prevented, as Berard has pointed out, by adhesions of their walls to surrounding parts.* The pressure of the blood in the veins will be augmented by a general increase in the quantity of blood in the system, and by increase in the force and frequency of the heart's beats, except that such increase would, in the first instance, occasion more rapid and complete depletion of the venous system. The blood-pressure in the pulmonary artery has been investigated by several observers, and has been found to be 3 times less than that in the carotid in the dog, 4 times less in the rabbit, and 5 times less in the cat. Other estimates are that the pressure in the pulmonary artery is to that of the aorta as 1 : 3; as 1 : 2·5; and 1 : 1·85. Hering, in a case of ectopia cordis in a calf, introduced glass tubes of equal diameter through the walls of the two ventricles, and found that the blood rose 21 inches in that in the right ventricle, and 33·4 inches in that in the left ventricle, which is in the proportion of 1 : 1·6. An agency which certainly assists the venous circulation in some animals is the rhythmical contraction of the walls of the Veins which has been observed to occur 8 to 10 times per minute in the transparent membrane of the wing of the Bat, the amount of contraction being about one-fourth of the diameter of the vessel (Wharton Jones). The same phenomenon repeated 5 or 6 times per minute has been observed by Schiff† and Vulpian‡ in the veins of the ear, and by Wagner§ in the vessels of the iris of the rabbit. It has also been shown by Mr. Wharton Jones|| that the lymphatic hearts of the eel and frog are to be regarded as exerting an auxiliary agency on the general circulation, propelling their contents at certain intervals into the veins. The walls of these hearts are composed of unstriped rhythmically contractile muscular fibrils which contract under the influence of the spinal cord.¶

253. One of the most powerful of the general causes which influence the Venous circulation is doubtless the frequently-recurring *pressure of the muscles* upon their trunks. When quiescent the circulation in muscles is extremely slow, but whenever contraction takes place, a portion of the Veins of the part will undergo compression; and as the blood is prevented, by the valves in the Veins, from being driven back into the small vessels, it is necessarily forced on towards the heart.** As each set of muscles is relaxed, the veins compressed by it fill out again, to be again compressed by the renewal of the force. That the general Muscular movement is an important agent in maintaining the circulation at a point above that at which it would be kept by the action of the heart and arterial system alone, appears from several considerations. The pulsations are diminished in frequency by rest, accelerated by exertion, and very much quickened by violent effort. In all kinds of exercise, and in almost every sort of effort, there is that alternate contraction and relaxation of particular groups of muscles, which has been just mentioned as affecting the flow of blood through the veins; and there can

be little doubt that the increased rapidity of the return of blood through them is of itself sufficient cause for the accelerated movements of the heart. When a large number of muscles are put in action after repose, as is the case when we rise up from a recumbent or a sitting posture, the blood is driven to the heart with a very strong impetus; and if that organ should be diseased, it may arrive there in a quantity larger than can be disposed of; so that sudden death may be the result. Hence the necessity for the avoidance of all sudden and violent movements on the part of those who labour under either functional disorder or structural disease of the centre of the circulation.

254. The Venous circulation is much more liable than the Arterial to be influenced by the force of gravity; and this influence is particularly noticeable when the tonicity of the vessels is deficient.—The following experiments, performed by Dr. C. J. B. Williams,* to elucidate the influence of deficient firmness in the walls of the vessels, and of gravitation, over the movement of fluids through tubes, throw great light on the causes of *venous congestion*:—A tube with two equal arms having been fitted to a syringe, a brass tube two feet long, having several right angles in its course, was adapted to one of them, whilst to the other was tied a portion of a rabbit's intestine four feet long, and of calibre double that of the brass tube, this being arranged in curves and coils, but without angles or crossings. When the two tubes were raised to the same height, the small metal tube discharged from two to five times the quantity of water discharged in a given time by the larger but membranous tube; the difference being greatest when the strokes of the piston were most forcible and sudden, by which the intestine was much dilated at its syringe-end, but conveyed very little more water. When the discharging ends were raised a few inches higher, the difference increased considerably, the amount of fluid discharged by the gut being much diminished; and when the ends were raised to the height of eight or ten inches, the gut ceased to discharge, each stroke only moving the column of water in it, and this subsiding again, without rising high enough to overflow.—When the force of the stroke increased, the part of the intestine nearest the syringe burst. From these experiments it is easy to understand how any deficiency of "tone" in the Venous system will tend to prevent the ascent of the blood from the depending parts of the body, and will consequently occasion an increased pressure on the walls of the vessels, and an augmentation in the quantity of blood they contain. All these conditions are peculiarly favourable to the escape of the watery part of the blood from the small vessels; and this may either infiltrate into the areolar tissue, or it may be poured into some neighbouring serous cavity, producing dropsy. Thus it happens that such effusions may often be traced to that state of deficient vigour of the system which peculiarly manifests itself in want of tone of the blood-vessels; and that it is relieved by remedies which restore this. In many young females of leuco-phlegmatic temperament, for example, there is a tendency to swelling of the feet, by œdematous effusion into the areolar tissue, in consequence of the depending position of the limbs; the œdema disappears during the night, but returns during the day, and is at its maximum in the evening. And the congestion which frequently manifests itself in the posterior parts of the body, towards the close of exhausting diseases in which the patient has lain much upon his back, is attributable to a similar cause; of such congestion, effusions into the various serous cavities are frequent results; and such effusions, taking place during the last hours of life, are often erroneously regarded as the source of death. To the same cause we are to attribute the varicose state of the veins of the leg, which is so common amongst

* "Principles of Medicine," 2nd edit., p. 188.

persons of relaxed fibre, and especially in those whose habits require them to be much in the erect posture; and this distension occasionally proceeds to complete rupture, the causes of which are fully elucidated by the experiments just cited. A peculiar humming sound may be heard in the veins of the neck when a stethoscope is placed and slight pressure exercised just above the clavicle, especially on the right side.* This may either be continuous or be rhythmical and synchronous with the diastole of the heart or with the act of inspiration. It is caused by the vibration of the walls of the vessels, caused by the eddy of the blood flowing from the narrower portion of the jugular above into the larger channel presented by its dilatation below; as a pathological symptom it is particularly perceptible in those in whom the walls of the veins are flaccid, as in anæmic patients.

255. Attempts have been made to ascertain the mode in which the blood is distributed through the body, the methods employed having been either by freezing the subject and determining the quantity of blood in each part, or by rapidly removing the several organs during life, and collecting the blood which flows from them and that which they still retain. Neither method gives more than approximative results; but, proceeding in this way, Ranke estimated that in the living and quiescent rabbit the blood was nearly equally divided between the muscles, the liver, the heart and arteries, and the whole of the remaining organs. The quantity in each part of the body is, however, undergoing constant alteration, the variation being essentially dependent upon its functional activity. The difference has been observed to amount to as much as 30 or even 47 per cent. Well-marked examples of great differences in the quantity of blood present may be observed in quiescent and active glands, in the full and empty stomach, and a principle of compensation may be noticed to occur in many organs—the mind, for example, being less active during digestion; the kidneys secreting less when the vessels of the skin are dilated and free transpiration is taking place. The variations in the quantity of blood in an extremity may be demonstrated by an instrument named a Plethysmograph, constructed by Mosso, and which consists essentially of a glass cylinder, into which the arm or leg can be introduced, and by means of a caoutchouc band be made to fit water-tight to it. The space between the limb and the tube is filled with water, the pressure of which can be increased or diminished by raising or lowering a vessel filled with water; in connection with the cylinder is also a manometer, to which is attached a registering apparatus. The variations of volume exhibited by the extremity in the cylinder are found to be referable to the arterial pulsations, the curves of which resemble those of the pulse; secondly, to respiratory movements, strong inspiration augmenting the venous current and enfeebling the arterial flow, and *vice versâ;* active respiration and arrest of respiration alike cause diminution of volume, whilst it is increased by straining and coughing; thirdly, to variations in the activity of the vaso-motor ganglia, causing periodic variations of volume by modifying the size of the smaller arteries; fourthly, to differences in the position of the limb, causing variation of hydrostatic pressure; fifthly, to muscular activity or quiescence, the former facilitating the flow of blood through the veins; sixthly, to mental activity, which, by withdrawing blood to the large intracranial plexus of vessels, diminishes the volume of the extremities; lastly, to compression of the arteries or veins.

* Landois, "Lehrbuch der Physiologie, 1879, p. 191.

6. *Peculiarities of the Circulation in different Parts.*

256. In several portions of the Human body there are certain varieties in the distribution and in the functional actions of the blood-vessels which should not be omitted in a general account of the Circulation.—Of these, we have in the first place to notice the apparatus for the *Pulmonary* circulation; the chief peculiarity of which is, that *venous* blood is sent *from* the heart, through a tube which is arterial in its structure, whilst *arterial* blood is returned *to* the heart, through a vessel whose entire character is that of a vein. The movement of the blood through these is considerably affected by the physical state of the lungs themselves; being retarded by any causes which can occasion pressure on the vessels (such as over-distension of the cells with air,* obstruction of their cavity by solid or fluid depositions, or by foreign substances injected into them, &c.); and proceeding with the greatest energy and regularity when the respiratory movements are freely performed.—The *Portal* circulation, again, is peculiar, in being a kind of offset from the general or systemic circulation, and also in being destitute of valves; and it may be surmised, with much probability, that the purpose of their absence is to allow of an unusually free passage of blood from one part of that system to another, during the very varying conditions to which it is subjected. The Vena Portæ resembles other veins in being formed by the union of smaller veins, and it receives the venous blood which has traversed the capillaries of the stomach, intestines, and spleen; but, instead of opening directly into the Vena Cava, it is peculiar in breaking up, when it arrives at the liver, into a second system of capillaries, which are distributed throughout that organ; and it is only after the hepatic capillaries have reunited to form the Hepatic vein that the blood is transmitted to the heart through the Vena Cava. The presence of the second set of capillaries renders the circulation slower in the portal system of vessels than in any other part of the body.—The *Renal* circulation, again, presents certain peculiarities that resemble those of the portal circulation. In this case the arteries divide and subdivide, till at length a small afferent branch enters the dilated extremity of a urinary tubule and here forms a *glomerulus*, or convoluted mass of capillaries, which may be compared to the capillary plexus on the walls of the intestines. From the glomerulus issues an efferent artery, comparable to the Vena Portæ, which again breaks up into a capillary plexus surrounding the urinary tubules, just as the Vena Portæ divides into capillaries, permeating the liver. Finally, the renal capillary plexus discharges its contents into veins which, becoming successively larger, form the renal vein.—Another very important modification of the Circulating system is that which presents itself within the *Cranium*. From the circumstance of the cranium being a closed cavity, which must be always filled with the same total amount of contents, the flow of blood through its vessels is attended with some peculiarities. The pressure of the atmosphere is here exerted, rather to keep the blood in the head than to force it out; and it might accordingly be inferred that, whilst the quantity of cerebral matter remains the same, the amount of blood in the cranial vessels must also be invariable. This inference appeared to derive support from the experiments of Dr. Kellie,† who found, on bleeding animals to death, that, whilst the remainder of the body was completely exsanguine, the usual quantity of blood remained in the arteries and veins of the cranium; but that, if an opening was made in the skull, these vessels were then as completely emptied as the rest.

* See Quincke and Pfeiffer, 'Ueber den Blutstrom in die Lungen,' Reichert und Du Bois-Reymond's "Archiv," 1871, p. 90.

† "Edinburgh Medico-Chirurgical Transactions," vol. i.

In the experiments performed by Küssmaul and Tenner,* it was found on trephining the skull and compressing the carotids, that the brain, especially after removal of the dura mater, became very pale, and retreated from the opening to so great an extent as to form a cup 2½ mm. in depth; whilst, on releasing the pressure, it assumed a deep rose colour and became convex. When, however, they luted a piece of glass air-tight into the hole made by the trephine, as suggested by Donders, the phenomena were no longer the same, for no movement of any kind could then be perceived in the brain, which remained in all cases immovably in contact with the glass plate; but the same changes in the tint of the cerebral substance, on checking and again restoring the current in the arteries, were observed. Observations of a similar nature were made by Mr. Durham† and Dr. Hammond,‡ by whom it was noticed that the condition of the brain varied to a remarkable degree in the sleeping and in the waking states, being paler and anæmic in the former, and comparatively congested in the latter. These experiments, therefore, appear to furnish indisputable evidence that the circulation of blood through the Brain varies with the general conditions of the vascular system, and is not, as Dr. Kellie's experiments appeared to show, independent of them. In M. Jolly's experiments a manometer luted into the skull of dogs showed a positive pressure, which, rising with expiration and falling with inspiration, was sufficient in general to support a column of water varying from one to six inches in height. In rabbits it was about half this amount, and occasionally became negative. The pulse in dogs caused a variation of from 5 to 10 mm. Compression of the carotids produced but little effect, but the pressure slowly rose when the jugular veins were compressed.§ Moreover, in disordered states of the circulation the quantity of blood in the vessels of the cranium may be for a time diminished by a sudden extravasation, either of blood or serum, into the cerebral substance; and the amount of interior *pressure* upon the walls of the vessels may also be considerably altered, even when there is no difference in the *quantity* of fluid contained in them.‖ It seems highly probable that in the delicate and extensive system of capillaries found in the pia mater and choroid plexus, a provision is made by which a large quantity of cerebro-spinal fluid can be effused or absorbed in a short space of time, to compensate for sudden changes in the balance of the circulation.

257. The *Erectile Tissues* present another curious modification of the ordinary vascular apparatus. The chief of these are the corpora cavernosa in the penis of the male, and in the clitoris of the female; the collection of similar tissues round the vagina and in the nymphæ and uterus (Rouget) of the female; and the nipple in both sexes. In all these situations, erection may be produced, and in the case of the penis, *emissio seminis* may be effected,

§ See F. Jolly, "Untersuchungen über den Gehirndrück und über die Blutbewegung im Schädel," Wurzburg, 1871; G. Althaun, "Beiträge zur Physiologie und Pathologie der Circulation," 1871. Pagenstecher, "Experimente und Studien über Gehirndrück;" and Cappie, "The Relation of the Cranial Contents to the Pressure of the Atmosphere," 1874; R. Vance, 'The Encephalic Circulation,' "New York Med. Record," 1877, p. 291.

‖ The results of the experiments of Dr. G. Burrows ("Medical Gazette," April and May, 1843) fully confirm the views stated above. Pagenstecher has shown that from 2·9 to 6·5 per cent. of the cubic capacity of an animal's skull may be occupied by injection of wax and tallow through a trephine aperture before symptoms of pressure supervene. In other words, that taking the capacity of the skull to be 1300–1400 cub. cm., from 37·7–40·6 cub. cm. as a mean, or 84·5–90·0 cub. cm. as maximum of blood may be effused without evidence of pressure.

by local irritation. The erectile tissue appears essentially to consist of a plexus of veins with varicose enlargements, enclosed in a fibro-muscular envelope with trabecular partitions.* In the penis, as first pointed out by Prof. Müller,† there are two sets of arteries; those of one set, destined for the nutrition of the tissues, communicating with the veins in the usual way, through a capillary network; whilst the others, termed by him the "helicine arteries," are short, tendril-like branches which project into the veins (covered, however, by their endothelium), sometimes singly, and sometimes in tufts, ending abruptly by dilated extremities. These arteries are accompanied by a special system of longitudinal bundles of muscles, the fibres of which become inserted into the middle coat at various points (Stilling, Stein). The dilated ends of the helicine arteries usually communicate directly with the venous cavities, since injection thrown into the former generally fills the latter, and Kölliker states that he has frequently found them giving-off delicate, almost capillary vessels, which discharge themselves into the venous spaces. The nerves implicated in producing erection in the dog were found by Eckhard‡ to be, first, the *Nn. pudend. communes* proceeding from the sciatic plexus, and supplying the musculi ischio-cavernosi, the corpora cavernosa of the penis, and membranous portion of the urethra; and, second, the *Nervi erigentes* proceeding from the sacral nerves and entering the hypogastric plexus. This plexus contains minute ganglia, communicates with the posterior mesenteric plexus, and furnishes branches to the bladder, prostate gland, rectum, and membranous portions of the urethra. After division of the former, or common pudendal nerves in the dog, Eckhard found it impossible to produce erection of the penis or emission of semen by direct irritation of the penis. The Nervi erigentes are, undoubtedly, the chief excitors to erection, for on exposing and irritating them, swelling of the penis, gradually proceeding forwards to the glans, immediately commenced. Erection may also occur as a result of certain emotional conditions of the mind, the influence of which is probably transmitted through the Sympathetic nerve, as it may be experienced even in cases of paraplegia; whilst, according to Legros,§ after section of the sympathetic fibres distributed to an erectile organ no erection occurs. The precise mode in which the nerves act is still unknown,‖ but there are grounds for believing that both the male and female organs are preserved in a quiescent state by a tonic influence exerted over the vessels by centres situated in the lower part of the spinal cord. In the venereal orgasm, however, inhibitory centres are excited, which restrain the action of the spinal cord and lead to dilatation of the vessels and increased flow of blood through the organ; Eckhard, indeed, relates that in his experiments he obtained eight times more blood from the veins of the penis in a given time at the period of erection than during the intervals. The ischio-cavernosi and bulbo-cavernosus muscles probably afford

* See A. W. Stein, "New York Med. Journal," June, 1872, for an account of the Histology and Physiology of the Penis.

† 'Entdeckung der bei der Erection wirksamen Arterien,' in Müller's "Archiv," 1835, p. 202. The views of Müller, though opposed by Valentin (Müller's "Archiv," 1838, p. 182), Weber, Arnold, Béclard, and others, as well as recently by Rouget, "Journal de l'Anatomie," t. i. p. 326, and Langer, "Wien. Sitz.," xlvi. 1863, p. 120, who consider the helicine arteries to be for the most part, if not altogether, artificial products consequent on the difficulty of forcing injection into the tortuous vessels of the trabeculæ, have been supported by the great authority of Henle ("Handbuch d. Mensch. Anatom.," 1866, p. 402). See also Robin, pamphlet "On the Erectile Tissues;" Vulpian, "Leçons sur l'Appareil Vasomoteur," 1875, p. 161; Krause, "Histologie," 1876, p. 273; Toldt, "Lehrbuch der Gewebelehre," 1877, p. 484.

§ "Gaz. Méd. de Paris," 1866, No. 6.

‖ For different views see Kölliker, loc. cit.; Rouget, "Archives de Physiologie," 1868, p. 671; Goltz, Pflüger's "Archiv," Band vii. 1873, p. 346; Vulpian, "Leçons sur l'Appareil Vasomoteur," 1875, p. 161, et seq.

some assistance in completing and strengthening the act of erection by compressing the veins which return the blood from the penis, but they are clearly unable to effect it by their own act, and it is obvious that no analogous power can be exerted in other erectile organs, as the nipple. Their centres, according to Goltz,* are situated in the lumbar region of the spinal cord, and here also is in all probability an inhibitory centre governing their action as well as that of the *sphincter ani.*

CHAPTER IX.

OF RESPIRATION.

1. *Nature of the Function: and Provisions for its Performance.*

258. The Nutritive fluid, in its circulation through the capillaries of the system, undergoes great alterations, both in its physical constitution and in its vital properties. It gives-up to the tissues with which it is brought into contact some of its most important elements; and at the same time it is made the vehicle of the removal, from these tissues, of ingredients which are no longer in the state of combination that fits them for their offices in the Animal Economy. To separate these ingredients from the general current of the circulation, and to carry them out of the system, is the great object of the Excretory organs; the importance of whose respective functions will vary, it is very evident, with the amount of the ingredient which they have to separate, and with the deleterious influence which its retention would exert on the welfare of the system at large. Of all these injurious ingredients, Carbonic Acid is without doubt the one most abundantly introduced into the nutritive fluid; and it is also most deleterious in its effects on the system, if allowed to accumulate.—We find, accordingly, that the provision for the removal of this substance from the blood is one of peculiar extent and importance, especially in the higher forms of animals; and further, that instead of being affected by an operation peculiarly *vital* (like other acts of Excretion), its performance is secured by being made to depend upon simple *physical* conditions, and is thus comparatively little susceptible of derangement from disorder of other processes. All that is requisite for it is the exposure of the Blood to the influence of the atmospheric air (or, in aquatic animals, of air dissolved in water),† through the medium of a membrane that shall permit the "diffusion of gases;" an interchange then taking place between the gaseous matters on the two sides—Carbonic acid being exhaled from the Blood, and being replaced by Oxygen from the air. Thus, the extrication of Carbonic acid is effected in a manner that renders it subservient to the introduction of that element which is required for all the most active manifestations of vital power; and it is in these two processes conjointly, not in either alone, that the function of Respiration essentially consists.—We shall now inquire into the sources from which Carbonic acid is produced in the living body, and the causes of the demand for Oxygen.

259. The vital activity of the organism at large involves a continual change in its constituent parts; and those which (so to speak) live the fastest, usually

* Goltz, Pflüger's "Archiv," Band vii. 1873, p. 582.

† Whilst air contains about one-fifth of its volume of oxygen gas, water contains only one-two hundred and fiftieth of its volume. The feebleness of the respiratory processes which this implies in aquatic animals is in part compensated for by the ready solubility of carbonic acid gas in water, which facilitates its escape from the system, and the circumstance that the espiratory organs are actually floating in the oxygenated medium.

die the soonest, and pass most readily into decay (CHAP. X. SECT. 1). Hence in the very performance of the Organic functions which concur to effect the Nutrition of the body, there is a constant source of disintegration; and one of the chief products of the decay of the tissues, which is consequent upon their loss of vitality, is Carbonic acid.—The exchange of the Oxygen contained in the blood for the Carbonic acid generated in the tissues constitutes the process of "internal respiration," and takes place in all parts of the body. On the other hand, the exchange of the Oxygen contained in the air for the Carbonic acid constantly accumulating in the blood which takes place in the lungs and skin, constitutes the process of "external respiration." Thus, the *most general* object of the Respiratory process, which is common to all forms of organised being, is the extrication of this product from the system; and the demand for aëration hence arising, will vary with the activity of the nutritive operations. Now the rate of life, and consequently the amount of disintegration, in any organized structure, depend in great measure upon the temperature at which it is maintained; and thus it happens that the production of Carbonic acid from this source, at the ordinary rate of vital activity, is much more rapid in "warm-blooded" than in "cold-blooded" animals, and that the former suffer far more speedily than the latter from the privation of air. But when the temperature of the Reptile is raised by external heat to the level of that of the Mammal, its need for respiration increases, owing to the augmented waste of its tissues. When, on the other hand, the warm-blooded Mammal is reduced, in the state of hybernation, to the level of the cold-blooded Reptile, the waste of its tissues diminishes to such an extent as to require but a very small exertion of the respiratory process to get rid of the Carbonic acid, which is one of its chief products. And in those animals which are capable of retaining their vitality when they are frozen, or when their tissues are completely dried up, vital activity and disintegration are alike entirely suspended, and consequently there is no Carbonic acid to be set-free.

260. But another source of Carbonic acid to be set-free by the Respiratory process, and one which is peculiar to animals, consists in the rapid changes which take place in the Muscular and Nervous tissues, in the very act of performing their peculiar functions; the development of the Muscular and of the Nervous forces involving, as the very condition of their production, a change in the substance of these tissues respectively; in which change a large quantity of oxygen is consumed, and a large amount of carbonic acid is generated. Hence in Man, as in all Animals, in which the Nervo-Muscular apparatus constitutes the essential part of the organism, a powerful demand for Respiration is created by its activity; the amount of oxygen taken-in, and of carbonic acid exhaled, being determined, *cæteris paribus*, by the degree in which this apparatus is exercised.—That Carbonic acid is set-free ready-formed by the muscles, and is not exclusively generated by the oxidation of the products of their disintegration after the reception of these into the blood-current, has been shown by the experiments of Dr. G. Liebig,* who found that carefully-prepared frogs' muscles absorb oxygen and exhale carbonic acid so long as their contractility lasts, even when they have been completely deprived of blood. In the similar experiments more recently made by M. Paul Bert† it clearly appears that whilst the muscular tissue on account of its large mass plays the most important part in those internal processes which he has

* "Bericht d. Akad. d. Wissensch. zu Berlin," 1850, §§ 339–347.

† P. Bert, "Leçons sur la Physiologie comparée de la Respiration," Paris, 1870, p. 30, et seq. In these experiments M. Bert found that:—

termed the "respiration of the tissues," yet that analogous changes occur in every tissue and organ in the body.* It must not, however, be too hastily assumed that the phenomena here witnessed are those of simple oxidation, since the absorption of Oxygen and the extrication of Carbonic acid are probably only the first and last links in a long series of decompositions.

261. Besides these sources of Carbonic acid which are common to all Animals, there is another which is restricted (or nearly so) to the two highest classes, Birds and Mammals; these being distinguished by their power of maintaining a constantly-elevated temperature. A part of this heat is generated by the oxygenation of the components of their disintegrating tissues, and of their blood, the metamorphosis of which takes place at a very rapid rate; but where this is not sufficient, their power of maintaining their temperature depends upon the *direct* combination of certain elements of the food with the oxygen of the air, by the combustive process.—The quantity of Carbonic acid that is generated directly from the elements of the food seems to vary considerably in different animals, and in different states of the same individual. In the Carnivorous tribes, which spend the greater part of their time in a state of activity, it is probable that the quantity which is generated by the waste or metamorphosis of the tissues is sufficient for the maintenance of the required temperature; and that comparatively little of the carbonic acid set-free in respiration is derived from the direct combustion of the materials of the food. But in Herbivorous animals of comparatively inert habits, the amount of metamorphosis of the tissues is insufficient; and some part of the food, consisting as it does of substances that undergo combustion with great facility, probably enters into direct combination with the oxygen of the air, and thus compensates for the deficiency.† In Man and other animals, which can sustain considerable variations of climate, and can adapt themselves to a great diversity of habits, the quantity of carbonic acid formed by the direct combination of the elements of the food with the oxygen of the air, will differ under different circumstances. It will serve as the *complement* of that which is formed in other ways; so that it will diminish with the increase, and will increase with the diminution of muscular activity. It will also vary in an inverse ratio to the external temperature, increasing with its diminution (as more heat must then be generated), and diminishing with its increase; the effect of external heat being thus precisely opposite, in the warm-blooded animal, to that which it exerts on the cold-blooded.—In all cases, if a

Grammes.		Cub. cent. of Oxygen.	Cub. cent. of Carbonic Acid.
100 of muscle	Absorbed	50·8	Exhaled 56·8
„ of brain		45·8	42·8
„ of kidney		37·0	15·6
„ of spleen		27·3	15·4
„ of testis		18·3	27·5
„ of bone and marrow crushed		17·2	8·1

It is worthy of notice that M. Bert finds in corroboration of Spallanzani's experiments that the larger the proportion of oxygen present in the air to which the tissues are exposed, the more freely it is absorbed; the proportion of carbonic acid gas exhaled, however, is not correspondingly increased.

* The statement of MM. Estor and St. Pierre, that the formation of carbonic acid is most energetic in the arterial system (Robin's "Journal de l'Anatomie," 1865, p. 302), has been refuted by Hirschmann (Du Bois-Reymond's "Archiv," 1866, p. 502), and Hoppe-Seyler ("Med. Chem. Untersuch.," Berlin, 1867, p. 295).

† Thus Ludwig and Scheremetjewsky found that if an easily combustible substance like glycerin or lactate of soda be injected directly into the blood, the absorption of O and elimination of CO_2 were immediately and considerably increased (Ludwig's "Arbeiten," 1868).

sufficient supply of food be not furnished, the store of fat is drawn upon; and if this be exhausted, the animal dies of cold. To recapitulate, then, the sources of demand for Oxygen and production of Carbonic acid in the animal body are threefold.—I. The continual decay of the tissues common to all organized bodies, which is favoured by whatever promotes their vital activity, and is retarded by every influence that depresses it.—II. The metamorphosis peculiar to the Nervous and Muscular tissues, which is the very condition of the production of their power, and which, therefore, bears a direct relation to the degree in which they are exerted.—III. The direct oxidation of some of the constituents of the food which varies the proportion in accordance with the amount of heat to be generated.

262. The activity of the process of respiration in any animal is, as a general rule, in direct proportion to the smallness of the corpuscles of its blood; for these, as has already been shown (§ 176), are the carriers of oxygen; and it is evident that a given weight of smaller globules will offer a larger surface for the absorption of oxygen than an equal weight of larger corpuscles. Hence in Fishes and Reptiles, which possess larger corpuscles, the provision for the aëration of the blood is much less perfect, and the amount of oxygen absorbed, and of carbonic acid eliminated, is considerably smaller than in the case of Mammals and Birds, the corpuscles of whose blood are remarkably minute. At the same time, the size of the lungs in the latter classes is far less in proportion to their bulk than in most Reptiles; but this diminution is more than compensated by the minute subdivision of their cavities, by the peculiarity of the distribution of their blood-vessels, and by the arrangements whereby a continual and rapid interchange, both of the blood and of the air, is provided for.—The following are the points of most importance in the structure of the Human Lung:*—The walls of the larger *bronchi* are composed independently of the tunica adventitia of four structurally distinct layers. Of these the outermost (*a*, Fig. 162) is a fibrous layer of dense connective-tissue in which cartilaginous laminæ, conferring firmness and elasticity on the tubes, are imbedded. The next (*b*) is a muscular layer composed of compact circularly-arranged fasciculi of smooth muscular tissue. The third is the internal fibrous layer (*c*), composed of tolerably regularly-arranged longitudinal bundles of thick elastic fibres, which on section give a sinuous outline to the interior of the tube. The innermost part of this layer is condensed into a hyaline layer, and upon this last or so-called basement membrane rests the ciliated columnar epithelium that forms the fourth layer (*d*). Intervening here and there amongst the ciliated columnar cells are E. Schulze's *cup*, *goblet*, or *chalice cells* (*b*, Fig. 161). These are filled with the mucous mass through which numerous highly-refractile granules are distributed. Imbedded in the outer fibrous layer of the larger bronchi are numerous mucous glands, the ducts of which run inwards, are lined with columnar epithelium, and open by trumpet-shaped

external fibrous coat, and the absence in it of either cartilages or mucous glands, whilst the columnar ciliated epithelium becomes lower or more flattened, and finally at the termination of the bronchia in the alveolar passages the cells lose their cilia and the cup cells cease to appear. The bronchial tubes divide and subdivide, and at their termination (*a*, Fig. 163), open into canals known as the *alveolar passages*, the entrance of which is surrounded by a thick bundle of annular muscular fibre-cells forming a kind of sphincter.* The alveolar passages, *c*, *c*, are rather wider than the bronchia, from which they spring, and, after dividing dichotomously at acute angles from two to four times, terminate cœcally at a distance of from 1-12th to 1-6th of an inch from the extremity of each bronchial tube. In consequence of these ultimate processes gradually expanding towards their cæcal terminations they have been termed *infundibula*. Both the alveolar passages and the infundibula (air-sacs of Dr. Waters, which he describes rather differently from Schulze as forming a group of from 6 to 10 in number clustered around the extremity of every bronchial tube) are beset with numerous small polyhedric cavities with rounded angles and borders termed the *alveoli* or *air-cells* (Fig. 163); from ten to twenty of each may be counted on the interior of each infundibulum or air-sac. The length of the alveoli of ordinary size are about equal to their breadth; their total number has been estimated approximately at 1700 or 1800 millions, with a surface equivalent to 200 square metres (Küss).† The foundation layer of the alveolar wall is composed of a transparent structureless membrane, which in the thickest parts exhibits a distinctly fibrous character,

Fig. 163.

† "Physiologie," 1873, p. 338.

caused by the presence of numerous elastic* and muscular fibres.† The membrane is folded sharply at the margin of the air-vesicles (Fig. 164, *c*) so as to form a very definite border to them. The stronger septa divide off polyhedric portions of the alveolar parenchyma, which are known as *lobuli*. —The diameter of the human *air-cells* is about twenty times greater than that of the capillaries which are distributed upon their parietes; varying (according to the measurement of Weber) from the 1-200th to the 1-70th of an inch.‡ The inner surface as well as the whole of the infundibula and alveolar passages are invested by a continuous, and in the fœtus homogeneous, epithelium. In adult mammals, however, it is not homogeneous. In the mature fœtus the cells are flat, 4–6 angled, with granular contents, and a bright spherical nucleus. In the adult such cells are arranged in groups of two or four, separated by large, transparent, thin, structureless cells, which are either irregularly angular or sinuous in outline. These cover, though perhaps not quite continuously, the capillaries and all the folds and prominent edges. The granular spheroidal cells cover the alveolar walls between the meshes of the capillaries, and in adults constantly contain spheroidal black pigment granules. The capillary plexus (Fig. 165) is so disposed between the two layers which form the walls of two adjacent air-cells, as to expose one of its surfaces to each; by which provision the full influence of the air upon it is secured. The network of vessels is so close that the diameter of the meshes is scarcely so great as that of the capillaries which enclose them, and they often project into the cavity of the alveoli, either free or covered only by the flat cells above mentioned; indeed, it would be impossible to conceive of a method by which blood, whilst still retained within vessels, should be spread over a larger surface for aëration. And if not restricted

‡ The dimensions given by Moleschott ("De Vesiculis Pulmonum Malpighianis") are very much less than these; the range of diameter being stated by him at between 1 120th and 1–1200th of an inch. The Author's own observations, however, lead him to regard Weber's and Kölliker's statements as very near the truth.

within vessels, it could not be ceaselessly and rapidly driven-on by the propulsive power of the heart, which acts no less efficiently upon the pulmonary circulation than upon the systemic, although the force exerted is much inferior, the resisting power being far less, in consequence of the shortness of the circuit. Estimating the surface of the capillaries at three-fourths of the whole surface of the alveoli, a thin layer of blood of 150 square metres would be exposed to the air, representing about two litres of blood; and it has been further calculated that it is renewed 10,000 times in the 24 hours (Küss).* Even making great allowance for error in these calculations, enough remains to show how extensive is the surface for the interchange of gases between the air and the blood.—Two systems of vessels, the pulmonary and the bronchial, transmit blood, though in very different proportions, through the lungs. In the former, which is by far the largest, the blood received from the system, deficient in oxygen and charged with carbonic acid, is propelled by the right ventricle through the pulmonary artery to the minute plexus of capillaries just described on the walls of the air-sacs and vesicles. From thence, having undergone aëration, it is returned to the left auricle of the heart, through the pulmonary veins, to be distributed by the left ventricle and arterial system to the body at large. The smaller system, which has been particularly examined by Prof. Turner,† consisting of the bronchial arteries and veins, with numerous minute branches of the intercostal, internal mammary, and other arteries, is distributed to the parts about the root of the lung, the large bronchial tubes, and the pulmonic pleura; some of its capillaries discharge themselves into the corresponding bronchial veins, whilst others terminate in the pulmonary system, and, there is reason to believe, play an important part in maintaining the circulation in cases where the pulmonary artery has been obliterated by disease. The *lymphatics* of the Lungs‡ arise either from branched cells in the alveolar septa, one of the branches opening between the epithelial cells into the cavity of the alveoli (pseudo-stomata of Klein); or, as Sikorski maintains, from the goblet cells of Schulze. In either case they form a plexus in the submucosa, and then run with, and partially or wholly invaginate branches of the pulmonary artery and vein. Cloetta found in the lung tissue inosit, uric acid, taurin, and leucin, besides the ordinary chemical constituents of the glandular textures, as albuminous compounds, collagen, chondrin, protagon, elastin, and mucin. In the fœtus, the tissue of the lungs contains a large number of cells rich in glycogen, which escape on pressure in the form of a milk-white fluid, but which are not found except under pathological conditions in the adult.

263. The contractility of the bronchial tubes (according to the experiments of Dr. C. J. B. Williams§) may be excited by electrical, chemical, or mechanical stimuli, applied to themselves. It is chiefly manifested in the smaller bronchial tubes, those of less than a line in diameter having been seen to contract gradually under the stimulus of galvanism, until their cavity was nearly obliterated; on the other hand, in the trachea and the larger bronchi, the cartilaginous rings prevent any decided diminution in the calibre of the tubes, and the muscular structure is much less distinct. It is doubtful whether the contractility can be immediately and visibly called into play by irritation of the Pneumogastrics,‖ but there is reason to think that the general tone of the

§ "Report of the British Association for 1840," p. 411.

‖ Volkmann (Wagner's "Handwörterbuch," Band ii., Art. 'Nervenphysiologie,' p. 586), Longet ("Anat. et Physiol. du Système Nerveux," tom. ii. p. 289), and P. Bert ("Leçons sur la Physiologie comparée de la Respiration," Paris, 1870, p. 375) affirm that it can, whilst

muscular tissue in the lungs is dependent on this nerve. It is remarked by Dr. Williams, that the contractility of the bronchial muscles is soon exhausted by direct stimulation; but that it may in some degree be restored by rest, even when the lung is removed from the body. When the stimulation is long continued, however, as by intense irritation of the mucous membrane during life, the contractile tissue passes into a state which resembles the tonic contraction of muscular fibre. The contractility is greatly affected by the mode of death, and is remarkably diminished by the action of vegetable narcotics, particularly stramonium and belladonna; whilst it seems to be scarcely at all affected by hydrocyanic acid.—These facts are very important, as throwing light upon certain diseased conditions. It has long been suspected that the dyspnœa of Spasmodic Asthma depends upon a constricted state of the smaller bronchial tubes, excited through the nervous system, frequently by a stimulating cause at some distance; and there can be now little doubt that such is the case. The peculiar influence of stramonium and belladonna, in diminishing the contractility of these fibres, harmonizes remarkably with the well-known fact of the relief frequently afforded by them in this distressing malady. It seems not improbable that the contractility of the bronchial tubes may serve to regulate the supply of air to the lobules, in accordance with the wants of the system, just as the contractility of the minute arteries regulates the supply of blood to the organs to which they proceed; and it may possibly be through this channel that the remarkable variation is effected in the amount of respiration, which adapts the quantity of heat produced to the depression of the external temperature. It has been further suggested by Dr. W. T. Gairdner,* that the contractility of the smaller bronchi may serve to expel collections of mucus which have accumulated in them, and which neither ciliary action nor the ordinary expiratory efforts suffice to displace.

264. The elasticity of the lungs, which in many animals, as the horse, is remarkably increased by the dense layer of elastic tissue by which they are invested,† plays an important part in the respiratory acts. Donders‡ estimates the expiratory force derived from the elasticity and muscular tension of the lungs, and coming into play in ordinary respiration, as equal to a pressure of about 5 ozs. on the square inch; but the elastic tension is rapidly increased by the dilatation of the lungs with air, and the carefully-conducted experiments of Dr. Hutchinson§ led him to estimate it at certainly not less than 8 ozs. upon each square inch of surface when the lungs have been filled by the deepest possible inspiration; so that its whole amount (reckoning an average surface of 300 sq. in. for the male, and 247 sq. in. for the female) will be not less than 150 lbs. for the male, and 123½ lbs. for the female. This force is exerted in aid of the *ex*piratory movement, and is directly antagonistic to the *in*spiratory;‖ so that the inspiratory muscles must overcome it, in order to produce complete distension of the pulmonary cavities. This distension is entirely accomplished by the action of the muscles external to the thorax, or partly forming its parietes.

Rosenthal ("Die Athembewegungen," p. 232), Rugenberg ("Studien des Phys. Institut zu Breslau," 1863, p. 47) and Wintrich ('Krankheit. d. Resp. Org.' in Virchow's "Handbuch der Pathol.," 1855–57) maintain that if a manometer be inserted into the trachea, irritation of the peripheric extremity of the Vagus never produces any increase of pressure, which would certainly occur if the capacity of the bronchi diminished.

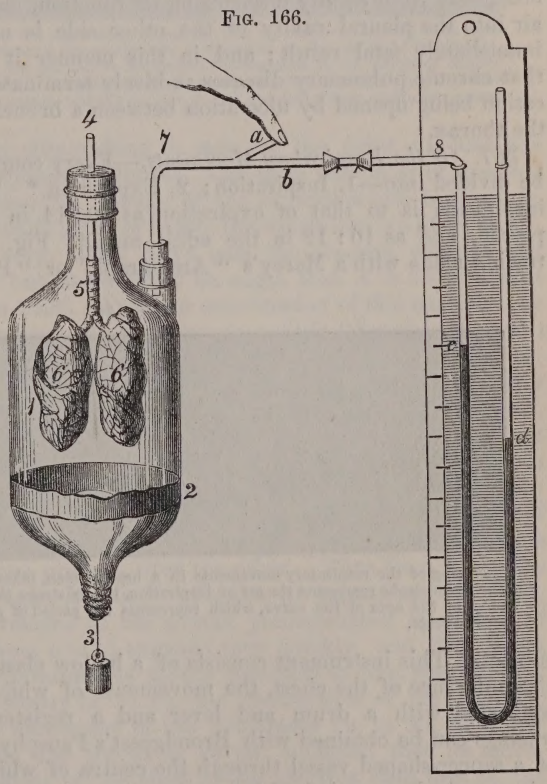
‖ Thus being directly opposed to the action in birds.

265. The mechanism of the respiratory acts may be rendered clearly intelligible by the accompanying diagram, in which the trachea and lungs (5, 6, Fig. 166) are enclosed in a glass vessel with three openings. The lower opening (2) is closed by a bladder or piece of caoutchouc, representing the diaphragm, and capable of being either pushed into the cavity of the vessel or of being drawn down by a weight. The upper opening is closed by a cork, through which a glass tube (4), firmly attached to the trachea, passes. The lateral opening (7) is connected with a manometer (*c*, *d*) by a tube (*b*), having a small lateral branch (*a*) opening to the air. If the openings (*a* and 4) be now stopped whilst the bladder is extended by the weight (3), the rarefaction of the air in the glass vessel will be made apparent by the rise of the mercury in the arm (*c*) of the manometer. It is obvious that the pressure of the air within and without the lungs will be different, and consequently, on opening the orifice of the tube (4) air will rush through it and the trachea to equalise the pressure as far as the elasticity of the lung will permit. Such, with the exception that in the living body no air intervenes between the surface of the lung and the walls of the thorax, and therefore no rarefaction, but only a tendency to a vacuum occurs, are the conditions present in the ordinary act of inspiration. On the contrary, with the same exception, the act of expiration may be imitated by pushing the bladder into the vessel; for then the pressure on the exterior of the lungs will be increased, the mercury in the arm (*c*) of the manometer will descend, and, aided by their own elasticity, for the lungs are always on the stretch, they will contract upon and drive out the air contained within their cavities.

Fig. 166.



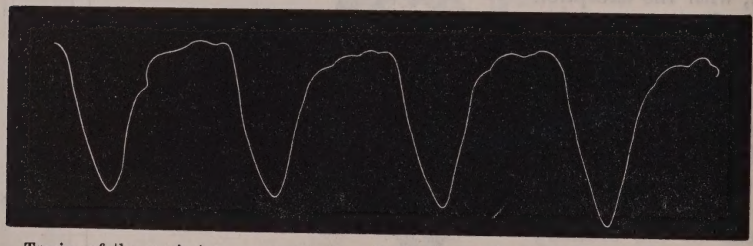
Apparatus constructed by Donders to show the Mechanism of Respiration.

266. The complete dependence of the expansion of the Lungs upon the enlargement of the cavity of the chest is well shown by the effect of admission of air into the pleural cavity. When an aperture is made on either side (as by removing the finger from the orifice of the tube *a* in the apparatus represented in Fig. 166), so that the air rushes in at each inspiratory movement, the expansion of the lung on that side is diminished, or entirely prevented, in proportion to the size of the aperture. If air can enter through it more

readily than through the trachea, an entire collapse of the lung takes place; and by making such an aperture on each side, complete asphyxia is produced. But if it be too small to admit the very ready passage of air, the vacuum produced by the inspiratory movement is more easily filled by the distension of the lungs than by the rush of air into the pleural cavity; so that a sufficient amount of change takes place for the maintenance of life. This is frequently observed in the case of penetrating wounds of the thorax, in the surgical treatment of which it is of great importance to close the aperture as completely as possible; when this has been accomplished the air that had found its way into the cavity is soon absorbed, and the lung resumes its full play. Where one lung is obstructed by tubercular deposit, or is prevented in any other way from rightly discharging its function, an opening that freely admits air into the pleural cavity of the other side is necessarily attended with an immediately fatal result; and in this manner it not unfrequently happens that chronic pulmonary diseases suddenly terminate in Asphyxia, a communication being opened by ulceration between a bronchial tube and the cavity of the thorax.

267. *Of the Respiratory Movements.*—Every complete act of respiration may be divided into—1, Inspiration; 2, Expiration.* The duration of the act of inspiration is to that of expiration as 10 : 14 in the child, female, and old person, and as 10 : 12 in the adult male.† Fig. 167 represents a normal tracing made with a Marey's "Atmograph" or "Pneumograph" in a healthy

FIG. 167.



Tracing of the respiratory movements in a healthy man, taken by M. Marey's Pneumograph. The down-stroke represents the act of inspiration, the up-stroke that of expiration. The undulations at the apex of the curve, which represents the period of *pause* of Longet, are due to the cardiac beats.

subject. This instrument consists of a hollow elastic cylinder applied to the circumference of the chest, the movements of which it follows. The tube is connected with a drum and lever and a registering apparatus. Similar tracings can be obtained with Brondgeest's Pansphygmograph, which consists of a saucer-shaped vessel through the centre of which a hole is bored, and a tube attached connected with a registering apparatus. The vessel is covered with a double layer of caoutchouc between which a sufficient quantity of air is introduced to cause it to be slightly prominent. This is applied firmly, by means of bands to the chest-wall, and the movements of the chest are then easily registered. A minute investigation of the variations of pressure in ordinary respiration has been made by Ewald with a specially modified manometer, and the accompanying diagram represents an analysis of a normal

* The pause which was admitted by Vierordt and others to occur between Expiration and Inspiration, has been shown by Riegel (Wurzburg. "Med. Gesell.," Band vii. 1867, p. 321), with a self-registering apparatus, not to be present, at least when the body is in a horizontal position.

† Sibson, "Med.-Chir. Transact.," vol. xxxi., and "Medical Anatomy."

espiratory pressure curve. In the first place the very regular transition of nspiration into expiration may be observed. The line D to F crossing the abscissa without the slightest notch or indent, which can only result from the

FIG. 168.

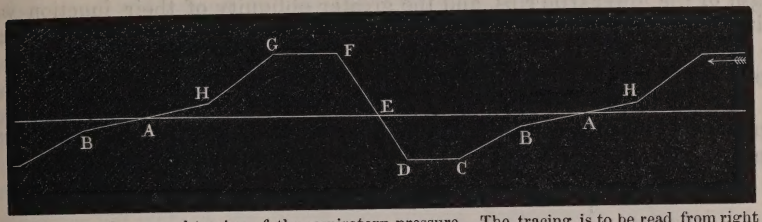


Diagram of a normal tracing of the respiratory pressure. The tracing is to be read from right to left. The part below the horizontal line or abscissa corresponds to the period of inspiration, and indicates negative pressure; the part above the abscissa corresponds to the period of expiration, and indicates positive pressure. The point where the curve cuts the abscissa is the moment where inspiration passes into expiration, and the point A is the moment where expiration passes into inspiration.

inspiratory pressure steadily diminishing to zero (at the point E), and the expiratory pressure rising equally uniformly. The same regularity is observed in the line H to B, representing the passage of the expiration into inspiration. This takes place more gradually; that is to say, the expiration is a little longer, but in exactly the same way. The curve cuts the abscissa without any indent, as a straight line, but at so slight an angle that it is often almost coincident with the abscissa itself. From an examination of this curve it may further be seen that the period of expiration is a little (though not much) longer than that of inspiration, the proportion being about as 12 : 11. Inspiration begins very gradually, the cavity of the chest increasing most rapidly at the end of the second third of the inspiratory period. On the other hand, in expiration the pressure is greatest at the end of the first third, and then gradually diminishes. Two nearly symmetrical indents, B and H, are seen in the ascending and descending curves. These Ewald regards as an expression of the fact that the chest cavity is more rapidly dilated by the movements of the thorax than by the contraction of the diaphragm. These two movements are indeed combined, but one prevails over the other. Thus from A to B the contraction of the diaphragm is chiefly effective in expanding the chest, whilst from B to E the movement of the thorax predominates, by means of which the thorax first (from B to C) expands very quickly, and then (from C to D) more slowly. In expiration the thorax contracts at first very quickly (from E to F), then more slowly (F to G), the contraction of the thoracic walls first acting, and the movement of the diaphragm (H to A), then first becoming perceptible, when the thorax is so far collapsed that its movement in diminishing the cavity of the chest is less effective than that of the diaphragm. In ordinary tranquil breathing (especially in children), the action of the diaphragm is alone nearly sufficient to produce the necessary exchange of air, and this muscle is consequently the chief inspiratory agent; but when a full inspiration is required, the cavity of the chest is dilated laterally and antero-posteriorly, as well as inferiorly.* The enlargement of the chest in both these directions is effected by the elevation of the ribs; for whilst, in the undilated state of the thorax, the ribs form an angle with their cartilages,

* Bert ("Leçons," p. 352) has clearly shown by tracings with his "Tambour pour recueillir les Mouvements du Thorax," or Pneumograph, that in the dog the diaphragm in contracting causes the 6th and lower ribs to rise, and thus to increase the transverse diameter of the chest; whilst, on the contrary, the 5th and upper ribs tend to descend and diminish the transverse diameter.

which become less and less obtuse as we pass from the first rib downwards, the elevation of the ribs tends to bring them and their cartilages more nearly into a line, and thus separates them more widely from the median plane, and at the same time causes them to push forward the sternum. Owing to the greater length of the lower true ribs, and the greater obliquity of their junction with their cartilages, both these changes are more considerable in the lower part of the thorax than in the upper; and this is especially the case in adult men, whose respiration has been designated as "inferior costal," whilst in females the mobility of the first rib and of the whole of the upper part of the thorax is greater, so that their respiration may be designated as "superior costal."—The respiratory muscles and nerve-supply are as follows:—

	Inspiration.		*Expiration.*

* Hutchinson, Op. cit., p. 1055. See also Cleland, "Journal of Anat. and Physiol.," vol. i. 1867, p. 209. There is probably no point in the whole range of physiology respecting which such different opinions have been entertained by good observers as upon the action of the intercostal muscles, and it may be instructive to give the following enumeration of them, drawn from Beau and Massiat ("Archiv. Gén. de Méd.," 1842), Küss ("Physiologie," 1873, p. 343), Budge ("Compendium de Physiol. Humain," 1874, p. 55), and Colin ("Traité de Physiologie Comparée," 1873, p. 251, *et seq.*:—1. Both the external and internal intercostals are *inspiratory muscles* (Borelli, Senac, Boerhaave, Winslow, Haller, Cuvier, Colin, Wündt, Duchenne, Duval); Duchenne supports his opinion by reference to a case in which all the respiratory muscles were paralysed except the intercostals, and yet in which respiration was maintained; Duval rests his upon experiments made on decapitated criminals shortly after death. 2. Both sets of muscles are *expiratory* (Vesalius, Diemerbröck, Sabatier, Beau and Massiat, Longet). This view rests on the fact that in vivisections the muscles may be seen to contract in forced expiration, as in coughing or crying out. Moreover, the intercostals are present in Birds, in which the act of expiration alone is due to muscular effort. 3. The *external* intercostals are *expiratory;* the *internal, inspiratory* muscles (Galen, Bartholinus). 4. The *external* intercostals are *inspiratory;* the *internal, expiratory* muscles (Spigelius, Vesling, Hamberger, and, with some modification, Sibson, Hermann, Cleland, and Foster). According to Sibson the external intercostals are inspiratory, except at their anterior part, in the five inferior intercostal spaces; the internal intercostals are inspiratory in the anterior part of the five first spaces, but have elsewhere an expiratory action. Hermann observes that the external muscles are *inspiratory* where they are attached to the osseous portions of the ribs, the internal where attached to the cartilaginous portions; but as this corresponds to the chief action of the two sets of fibres both may be regarded as inspiratory muscles. Cleland (Letter to Editor) remarks similarly that the external and anterior fibres of the internal intercostal are most advantageously disposed for elevating the ribs, and that the remaining intercostals are most advantageously placed for depressing the ribs; but that all the intercostals are capable of giving some assistance in inspiration, as also in forced expiration, whilst ordinary expiration is accomplished altogether by elasticity, and not by muscular effort at all. Aeby ("Lehrbuch," 1871, p. 379) holds that both sets of muscles approximate the adjoining ribs, but whether this occasions an elevation or depression of the whole series is dependent on the coincident action of other muscles. 5. Mayo and Magendie,

The movements of the heart have a slight influence on the lungs, the systole aiding inspiration, the diastole expiration.*

268. The *extent of movement* of the several parts of the chest during the respiratory acts may be registered by an instrument suggested by Dr. Burdon Sanderson,† and named by him the 'recording stethometer.' From experiments made with this instrument he finds that in the ordinary respiration of a healthy, muscular, young man, aged twenty-two, the upper antero-posterior diameter, which was equal to 146 mm., varied one mm.; the lower sternal diameter, which equalled 203 mm., varied 1·5 to 1·8 mm.; and the transverse costal diameter at the level of the eighth rib, which equalled 228 mm., varied 1·7 to 2·0 mm. In forced respiration the variations of the antero-posterior diameters of the upper part of the chest were much more extensive, the ends of the upper ribs moving horizontally forward—*i.e.*, in a plane parallel to the middle plane of the body, from 12–30 millimetres: the advance of the third rib being greater by several millimetres than that of the fifth, and this Dr. Ransome attributes to an actual straightening of the ribs.‡ The following Table, based on Riegel's experiments, gives the relative movement of the different points of the front of the chest in six men and six women, and shows well the contrast between the sexes:—

MAN.	Manub. Sterni.	Corp. Sterni.	Process. Ensif.	Epigast.
I.	1	1	1·5	4·5
II.	1	1	1·1	6·6
III.	1	1·3	10·0	12
IV.	1	1·8	3·7	11·4
V.	1	1·2	1·5	6·8
VI.	1	1·1	1·8	7·2
WOMAN.				
I.	1·8	1·1	1	0·73
II.	1·5	1·2	1	0·63
III.	1·4	1·3	1	1·5
IV.	5	3·1	1	1·9
V.	1·1	1	1	1·6
VI.	3·8	2·5	1	1·8

The extent of the respiratory movements is affected by various morbid conditions. Thus, when dislocation of the spine takes place above the origin of the intercostal nerves, but below that of the phrenic, so that the former are paralysed, the respiratory movement is confined to the diaphragm: this is insufficient, and with the coincident paralysis of the vaso-motor nerves leads to the effusion of serum into the lungs, and slow asphyxia, which usually proves fatal in a few days. Even where the muscles and nerves are all capable of action, the full performance of the inspiratory movements may be prevented by the solidification or engorgement of any part of the lung which interferes with its free distension; or by adhesions between the pleural surfaces, which offer a still more direct impediment. When these adhesions are of long stand-

and Volkmann ("Centralblatt," 1877, p. 115) regard both sets of muscles as at once expiratory and inspiratory in their action. Lastly, Van Helmont, Arantius, Cruveilhier, Küss, and Jobelin consider that both sets of muscles are passive in the movements of respiration, and simply form an immovable wall to the chest, or rather they contract, not to produce the movements of inspiration or expiration, but to resist at both periods the pressure either of the external or of the internal air.

* See Voit and Lossen, "Zeitschrift für Biologie," Band i.; Ceradini, "Verhand. des natur.-hist.-med. Vereins zu Heidelberg," 1869. Also Landois, who, however, holds a different opinion ("Berlin Klin. Wochens.," 1870).

ing, they are commonly stretched into bands, by the continual tension to which they are subjected. If the impeding cause affect both sides, the movements of both will be alike interfered with; but if one side only be affected, its movements will be diminished, whilst those of the other remain natural; and the physician hence frequently derives an indication of great value in regard to the degree in which the lung has become incapable of performing its functions. It is to be remembered, however, that the action both of the diaphragm and of the elevators of the ribs may be prevented by pain, either in the muscles themselves or in the parts which they move; thus the descent of the diaphragm is checked by inflammation of the abdominal viscera or of the peritoneum; and the play of the intercostals by rheumatism, pleurisy, pericarditis, or other painful disorders of the parts forming the parietes of the thorax. In man the acts of respiration are properly effected through the nostrils, which are lined by a highly vascular membrane kept constantly moist by numerous glands, and by the lachrymal secretion, whilst its surface is greatly extended by the sinuosities of the turbinal bones. The inspired air is thus rendered moist and warm before reaching the sensitive larynx and lungs, and the coughs and colds so prevalent in this country in the winter and spring months might often be avoided if care were taken, especially on sudden exposure to cold air, to breathe through the nostrils instead of the mouth. The passage of air into and from the lungs is accompanied by a peculiar soft blowing sound, termed the *respiratory murmur* or *bruit*. The act of inspiration being more rapid and energetic than that of expiration is attended by a louder sound, which is most distinctly audible in young children and in thin persons. It probably arises either, as Dr. Salter* suggests, from the current of air striking against the angles of division of the bronchia, or as indicated by Dr. Waters,† from a slight constriction that exists at the mouth of each air-sac. Other causes that have been assigned to it are the separation of the moist septa of the alveoli, the general friction of the air against the walls of the bronchial tube, and the reverberation of the glottidean bruit (Sabatier; Cornil, 1873). The expiratory murmur is exclusively due to the friction of the air against the glottis (Chauveau).‡

269. The relative amount of muscular force which is required for the two respiratory movements respectively is affected in a very remarkable manner by the elasticity of the walls of the thoracic cavity and of the lungs themselves; for this (like the elasticity of the lungs) supplies a force which greatly aids the *ex*piratory movement, whilst it offers a corresponding opposition to the *in*spiratory. Here, also, the degree of force exerted increases very rapidly with the degree of distension. Thus, in a body experimented on by Dr. Hutchinson,§ the following were the relations between the amount of air forced in, the resisting elasticity, as shown by the height of mercury supported, the actual pressure upon each square inch of surface which this indicated, and the total pressure over the surface of the chest, reckoning its area at 206 square inches:—

Cubic inches.				*Pressure in height of Mercury.*	*Pressure per sq. in.*	*Total pressure.*
Air forced in	70	Resisting elasticity		1·00 inch.	7·8 oz.	104·4 lbs.
„	90	„	„	1·50 „	11·7 „	150·6 „
„	180	„	„	3·25 „	25·3 „	326·3 „
„	200	„	„	4·50 „	35·1 „	451·9

To this 451·9 lbs. must be added at least 128 lbs. for the elastic force of the lungs themselves at that degree of distension, making altogether 580 lbs.; and

* Pamphlet on "Cause of Respiratory Murmur," 1864. † "Med.-Chir. Rev.," 1865, p. 217.
‡ See Budge, "Compendium de la Physiologie," 1874, p. 69. § Op. cit., p. 1056.

as the subject of this observation could expire during life considerably more air than the highest amount forced into his chest after death, there can be little doubt (judging from the rapid ratio in which the elastic force increases when the distension is approaching its limits) that the muscular power required to overcome this, towards the close of a very deep inspiration, could not have been less than 1000 lbs. The co-operation of the elastic resistance with the expiratory movement, and its antagonism to the inspiratory, is doubtless the principal cause why the power of the expiratory muscles, as tested by the height of the column of mercury supported by the air, should always be greater than that of the inspiratory muscles;* and why the expiratory power should be very much greater when the chest has been well filled with air, than when it is comparatively empty. The following is given by Dr. Hutchinson as the range through which these powers may vary within the limits of health:—

Power of Inspiratory Muscles.		*Power of Expiratory Muscles.*
1·5 inch.	Weak	2·0 inches.
2·0 „	Ordinary	2·5 „
4·5 „	Remarkable	5·8 „
7·0 „	Very extraordinary	10·0 „

Lassar† gives nearly similar numbers. Other observers have, however, found the pressure exerted in inspiration and expiration to be much less. Valentin‡ stated it at 1-5th inch, Hg for ordinary inspiration and expiration; with quite tranquil respiration the numbers were – 4·0 and + 3·6 mm. Hg. Donders§ estimated it at – 3 mm. Hg for inspiration, and about 2 mm. Hg for expiration; and Ewald,‖ the latest writer, with improved methods, estimates the normal pressure in quiet breathing to be only 0·1 mm. Hg for inspiration and 0·13 mm. Hg for expiration. The expiratory power may be augmented by the habitual performance of movements in which they participate; and thus the inspiratory power is the preferable test of the *vis vitæ*. This has been found by Dr. Hutchinson to bear some relation to height, being greatest (on an average of a considerable number of cases) when the stature is 5 feet 7 or 8 inches; and diminishing above that height, as well as below it. Fick estimates that the work accomplished in effecting the inspiration of 600 c.c. is equivalent to 0·63 kilogrammetre, and Prof. Haughton estimates the daily work of the respiratory muscles at 21 foot-tons.¶

270. It is impossible to form a correct estimate, by observations on one's-self, of the usual number and extent of the respiratory movements; since the direction of the attention to them is certain to increase their frequency and amount. In general it may be stated, that from 16 to 20 alternations usually occur in a minute;** of these, the ordinary inspirations involve but little movement of the thorax; but a greater exertion is made at about every fifth recurrence. According to Quetelet, the infant at birth breathes—

	44 times per minute.

tions of the heart is about 1 : 5, 1 : 4½, or 1 : 4; and when this proportion is widely departed from, there is reason to suspect some obstruction to the aëration of the blood, or some disorder of the nervous system.* Thus in Pneumonia, in which a greater or less amount of the lung is unfit for its office, the number of respirations increases in a more rapid proportion than the acceleration of the pulse; so that the ratio becomes as 1 to 3, or even 1 to 2, in accordance with the degree of engorgement.† In Hysterical patients, however, a similar increase, or even a greater one, may take place without any serious cause; thus Dr. Elliotson‡ mentions a case in which the respiratory movements of a young female, through a nervous affection, were 98, or even 106, whilst the pulse was 104. On the other hand, the respiration in certain typhoid conditions and in narcotic poisoning becomes abnormally slow, owing to the torpid condition of the nervous centres, the proportion being 1 to 6, or even 1 to 8; and in such cases the lungs not unfrequently become œdematous, from a cause hereafter to be mentioned. M. Marey§ believes it may be shown that the frequency of the respiratory acts are, as in the analogous case of the heart, almost always diminished, whilst they are at the same time rendered deeper by the existence of any obstacle to their due performance; so that there is an evident attempt made to effect, within certain limits, the introduction of the same quantity of air into the lungs in a given time; and in an ingenious instrument he has devised, where, by the reversal of a valve, difficulty of breathing may be induced either during inspiration or expiration, he has observed that that act is prolonged in which the dyspnœa is made to occur.

271. We have now to inquire into the mode in which the muscular movements of respiration are kept up by nervous power. Though to some extent under the control of the Will, they are partly 'automatic' and partly 'reflex' in their nature. Their chief centres are placed on either side of the apex of the *calamus scriptorius*, being in close relation with, or forming part of, the nuclei of origin of the Pneumogastric nerves, which are the principal excitor nerves that convey the stimuli on which the reflex movements are dependent, whilst from the adjacent parts of the medulla oblongata and spinalis proceed the chief motor nerves by which they are carried into effect. The whole of the Encephalon may be removed from above, and the spinal cord (as far up as the origin of the phrenic nerve) from below without suspending the most essential of the respiratory movements; yet the destruction of these centres causes their immediate cessation, and as the arrest of respiration is incompatible with life, they were named by Flourens the 'noeud vital.' It is uncertain whether there are distinct centres for the expiratory and for the inspiratory muscles, but there is reason to believe that a respiration-regulating centre lies beneath the corpora quadrigemina.‖ The experience of every one informs him that the Respiratory movements are partly

* V. Ghert has shown that, during violent exertion, the respirations increase in frequency more than the pulsations; but that in the subsequent period of rest, the increased activity of the cardiac movements is more persistent than that of the respiratory. For a list of the number of Respirations per minute in a great number of different animals see P. Bert, "Leçons," p. 393, *et seq.*

† See a Paper by Dr. Hooker, an abstract of which will be found in the "British and Foreign Medical Review," vol. iv. p. 263. ‡ "Physiology," p. 215, *note.*

§ "Mémoires de la Soc. de la Biologie," 1865, p. 175. Bert ("Leçons," p. 410) shows that many statements, though accurate when the obstacle to respiration is slight, must be accepted with some reservation when the obstacle is great, the amplitude then decidedly diminishing.

‖ Dr. Martin and Booker, Foster's "Journal of Physiology," vol. i. 1878–79, pp. 131 and 170.

under the control of the will, though frequently unrestrainable by it. In ordinary circumstances, when the blood is being perfectly aërated, and there is a sufficient amount of arterial blood in the system to carry on the functions of life for a short time, we can suspend the respiratory actions during a few seconds without any inconvenience. If, however, we endeavour to prolong the suspension, the stimulus occasioned by the circulation of venous blood through the respiratory centres, and that conveyed by the excitor nerves to the Medulla oblongata, becomes too strong, and we cannot avoid making inspiratory efforts; and if the suspension be still further prolonged, the whole body becomes agitated by movements which are almost of a convulsive nature, and no effort of the will can then prevent the ingress of air.* It is easy to understand why, in the higher animals at least, and more especially in Man, the respiratory actions should have become thus placed under the direction of the will: since they are subservient to the production of those Sounds by which individuals communicate their feelings and desires to each other; and which, when articulate, are capable of so completely expressing what is passing in the mind of the speaker. The respiratory centres are, moreover, as Duchenne† has pointed out, in immediate contiguity to the hypoglossal nucleus governing the movements of the tongue; to the inferior nucleus of the facial, regulating the movements of the lips; and to the nucleus from which the cardiac branches of the spinal accessory and pneumogastric nerves arise, so that all these functions are brought into immediate relation with the respiratory acts; and in the disease known as glosso-labio-laryngeal paralysis these centres are affected successively, the tongue being first attacked, then the muscles of the palate, then the orbicularis oris, whilst the fatal termination of the disease is preceded by attacks of suffocation. That the respiratory movements, as ordinarily performed, are essentially independent of the Will, appears not only from our own consciousness, but also from cases of paralysis; in some of which the power of the will over the muscles has been lost, whilst the movements have been kept up by the automatic or reflex action of the respiratory ganglia; whilst in others, some of the respiratory muscles have been motionless during ordinary breathing, and yet have remained under the power of the will.‡ That consciousness is not a necessary link in the chain of causes which produce the respiratory movements, we are enabled to judge from the phenomena presented by the human being in sleep and coma, by anencephalous fœtuses, and by decapitated animals. This conclusion is confirmed by a case recorded by Dr. H. Ley,§ who had under his care a patient in whom the pneumogastrics appeared to be diseased; the lungs suffered in the usual way in consequence, and the patient had evidently laborious breathing; but he distinctly said that he felt no uneasiness in his chest. The *automatic* activity of the respiratory centres is excited by the circulation of venous blood through the vessels of the medulla oblongata,‖ the

* It is asserted by M. Bourdon ("Recherches sur le Mécanisme de la Respiration," p. 21) that no person ever committed suicide, though many have attempted to do so, by simply holding the breath; the control of the will over the respiratory muscles not being sufficiently great to antagonise the stimulus of the "besoin de respirer," when this has become aggravated by the temporary cessation of the action. But such persons have succeeded better by holding the face beneath the surface of water; because here another set of muscles is called into action, which are much more under the control of the will than are those of respiration; and a strong volition applied to these can prevent all access of air to the lungs, however violent may be the inspiratory efforts.

† Duchenne, "De l'Electrisation localisée," 1872.

‡ Such cases are mentioned by Sir C. Bell, in the appendix to his work on the "Nervous System of the Human Body."

real stimulus appearing to be a deficiency in the amount of oxygen supplied, though perhaps the presence of an excess of CO_2 in the blood may constitute an additional stimulus.*

272. The *reflex*, as opposed to the automatic activity of the respiratory centres is chiefly excited through the *Vagi* or Pneumogastric nerves, and especially through the branches of these nerves distributed to the larynx and lungs. Other sensory nerves, however, as the fifth, and the sensory nerves of the skin generally, may convey impressions which are reflected at the medulla to the muscles maintaining respiration; painful impressions usually leading to expiratory efforts, whilst slighter degrees of stimulation cause inspiratory movements. Under ordinary circumstances—that is to say, in tranquil breathing—it would appear that the deficiency of oxygen or the accumulation of carbonic acid and other products of disintegration in the blood acts as a stimulus alike to the vagal centres and to the sentient extremities of the Vagus distributed to the lungs. In the latter case the excitation is conveyed through the trunks of these nerves to the vagal centres in the medulla oblongata, from whence impulses are liberated which descend through the spinal cord and chiefly through its lateral columns† to the phrenic nerves, which causing the diaphragm to contract, an act of inspiration takes place. The Blood, now become oxygenated, ceases to be a stimulus to the vagal nuclei and nerves, the vagal centres become quiescent, the diaphragm relaxes, and the elasticity of the chest and lungs expels the air, and the act of expiration is effected.‡ The succession of these phenomena constitutes *Eupnœa* or normal respiration, but if from any circumstances, as the performance of active exercise, or exposure to a high temperature,§ the consumption of oxygen and production of carbonic acid are increased, the vagal centres and extremities are more strongly excited, they initiate more powerful impulses, and other motor nerves (such as the intercostals) besides the phrenics are excited. In cases where the blood is still less perfectly arterialised, as when the supply of air is insufficient, the vagal centres are still more strongly excited, and all the accessory muscles are then called into play. If an animal be made to breathe superoxygenated air, or if its blood be surcharged with oxygen by the vigorous performance of artificial respiration, the respiratory movements gradually cease, and the condition termed *apnœa* is established.‖ This state only lasts for a short period, and respiration again commences. Considerable difference of opinion exists in regard to the cause of apnœa, some¶ considering it to be due to the quiescence of the respiratory centres, which being well supplied with oxygen liberate no impulses to the respiratory muscles, whilst others** maintain that it is essentially due to muscular exhaustion, occurring only when the subject of the experiment is much distressed, and

* Formerly the presence and accumulation of CO_2 in the blood were believed to constitute the stimulus to the centres of respiration. Nasse maintained that a deficient supply of oxygen constitutes a stimulus, by causing the central ganglia to respond more readily to the ordinary and *à fortiori* to any extraordinary quantity of CO_2 in the blood, whilst their excitability is lowered when the proportion of oxygen in the blood circulating through them is increased.

† See Schiff, Pflüger's "Archiv," Band iv. p. 225.

‡ Breuer, "Sitz. d. Wien. Akad.," 1868, Heft xii., attempts to show that the mere act of inspiration leads to relaxation of the respiratory muscles, and is a stimulus to the nerves supplying the expiratory muscles, and *vice versâ*.

after its respiratory movements have become irregular. Hoppe-Seyler observes that the duration of the apnœa, when it lasts one minute or more, is far more than sufficient to reduce the blood to its ordinary condition as regards oxygen; he points out also that arterial blood is naturally saturated with oxygen, and maintains that respiration in oxygen or in compressed air causes little difference in the frequency or depth of the respiratory acts. Rosenbach explains the phenomenon of apnœa by referring it to inhibition of the respiratory movements, owing to the mechanical stimulation of the pneumogastric nerves in the process of artificial respiration, these nerves exerting a constricting influence on the vessels of the medulla oblongata, whereby the liberation of impulses to the inspiratory muscles is diminished. Perhaps we may admit two kinds of apnœa, one of which is due to slight increase in the amount of oxygen in the blood, whilst the other is attributable partly to contraction of the vessels of the medulla oblongata, caused by stimulation of the vagus, which prevents the liberation of motor impulses to the muscles of respiration. It is certain that apnœa may be observed in those who are performing, or who have first performed, some violent exertion, and it here undoubtedly appears to result from exhaustion of the respiratory muscles.

273. When the movements of respiration are performed with difficulty and unusual effort, *Dyspnœa* is said to exist. This condition may be established as a result either of a deficient supply of oxygen or of accumulation of CO_2 in the blood. Both conditions induce dyspnœa, and in addition cause increase of blood pressure and diminished absorption of oxygen; but the toxic influence of CO_2 is especially characterised by a reduction of the amount of CO_2 eliminated, and by rapidly supervening paralysis of the motor and sensory nerve centres; whilst a deficient supply of oxygen occasions violent convulsions shortly before death.* Dyspnœa from deficiency of oxygen can be produced by the inhalation of Nitrogen or Hydrogen; in such cases Pflüger has shown the oxygen is greatly diminished, whilst the carbonic acid is not materially increased, or may even be diminished.† Dyspnœa from excess of carbonic acid can be induced by making the animal breathe air surcharged with that gas, or by preventing its elimination from the system. Traube‡ produced dyspnœa by making an animal breathe a mixture of 28 per cent. of carbonic acid gas, 32 per cent. of oxygen, and 40 per cent. of nitrogen.§ Dyspnœa produced by such gases as carbonic oxide and nitrous oxide is due apparently to these gases withdrawing oxygen from the blood, whilst phosphuretted, arseniuretted, and sulphuretted hydrogen reduce the hæmoglobin, and after first exciting rapidly paralyse the respiratory centres. Hydrocyanic and hydrochloric acid gases, chlorine, sulphurous acid, and some other gases seem both to act destructively on the blood, and to destroy the functional activity of the vagal nuclei.

274. The important part played by the Vagi in the respiratory acts may be experimentally shown by their division, and the application of a stimulus to their proximal extremities. The trunks of the vagi are not endowed with much sensibility, for if pinched or pricked the animal does not exhibit nearly such

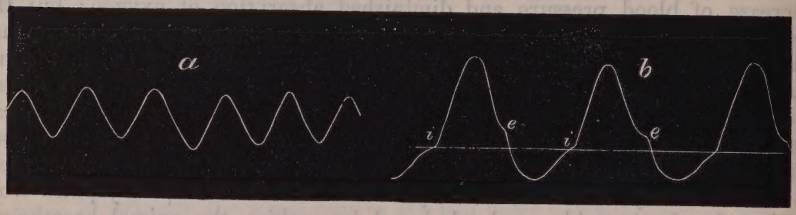
§ M. Bert ("Séance de la Soc. de Biologie," Feb. 3rd, 1872, "Rev. Scient.," 2e sér. i. année, No. 37, 1872, p. 882) has shown that the barometric pressure to which the animal is exposed is of great importance in such experiments, in consequence of its effects on the diffusion of the gases.

acute signs of pain as when the trunks of the ordinary spinal nerves or of the fifth pair are subjected to similar treatment. It has been clearly ascertained that they contain some fibres which have the power of inducing inspiratory and others which induce expiratory movements. The effects of section of the vagi appear to differ considerably in different animals, which is doubtless in part due to the fact that in some animals, as the Cat and Dog, the vagus is united into one trunk with the sympathetic and depressor nerves, the section of the latter leading to vaso-motor complications; whilst in others, as in Man and the Rabbit, these nerves are separate. When the section is made on one side only in the Rabbit the effects are not constant,* though the respiratory acts are usually rendered slower, but if the division be made simultaneously on both sides, the number of respirations per minute, as was shown by Dr. Reid,† diminishes from 120–140 to 40–50. The mechanism of breathing is at the same time completely altered. Each respiration becomes much deeper than before, which is partly due to increased action of the diaphragm, and partly to the participation of the accessory muscles in the act of inspiration. The inspiratory acts are often rendered sudden and spasmodic, with long intervening pauses, but usually the difference is such as is expressed in the following tracing given by Dr. Burdon Sanderson in which the movements are seen to be more slowly performed, but to be much fuller and deeper. The quantity

Fig. 169.



a. Tracing of the respiratory movements of the cat. *a* before *b* after division of both vagi.

of air breathed per minute is, however, not materially altered, being as great after as before the section, the diminished frequency being compensated for by increased depth of the respiratory act. Still it is to be particularly observed that although the vigour of the respiratory movements does not appear to be materially impaired, the blood becomes more or less venous (Sanderson).‡ In dogs the simultaneous division of the two vagi usually reduces the number of the respiratory movements by one-half (Reid). In pigeons the number falls to one-eighth, whilst the depth of each inspiration is only increased as 1 : 2·5, the respiratory activity therefore being diminished to about one-third of its original amount (Rosenthal).§ The influence of the Vagi upon respiration may also be shown by the application of an electrical stimulus of moderate intensity to the central extremity of the divided nerves of one side. The effect will be observed to vary according to whether the animal is breathing naturally, or is in a state of apnœa or dyspnœa. If it be breathing naturally, or be in a state of eupnœa, the immediate effect of slight irritation is an acceleration of the respiratory movements, whilst if the stimulus be stronger temporary arrest of respiration in inspiration occurs, owing either to contraction or to relaxation of the diaphragm without the participation of the

§ Rosenthal, "Comptes Rendus," 1861, p. 754.

other respiratory muscles.* If the excitation be still stronger, the respiratory movements are completely suspended, the diaphragm passing into a tetanic condition, which lasts as long as the stimulus is applied. In apnœa, when the blood is surcharged with oxygen, the effect is negative; in dyspnœa, when the blood is deficient in oxygen all the accessory muscles are brought into action, and the chest remains for a time in a state of tetanic expansion.† When the animal is depressed by chloral, and its nerves are exhausted, stimulation of the vagi, instead of being followed by contraction, is followed by relaxation of the diaphragm, which is regarded as the effect of the stimulation of the inhibitory fibres probably contained in the recurrents.‡

275. The motor power of the Respiratory nerves is exercised, however, not only on the muscles which perform the inspiratory and expiratory movements, but on those which guard the entrance to the windpipe, and also on some other parts. Between the superior and inferior Laryngeal nerves there is an important difference, which anatomical and experimental researches have now very clearly demonstrated. It appears from the very careful and satisfactory observations and experiments of Dr. J. Reid,§ that whilst the *inferior* laryngeal is the *motor* nerve of nearly all the laryngeal muscles, the *superior* laryngeal is an *afferent* nerve of extreme sensibility, conveying to the Medulla Oblongata the impressions made on its peripheral extremities. The motor endowments of the latter are limited to the crico-thyroid muscle, to which alone of all the muscles its filaments can be traced, the remainder being distributed to the mucous membrane of the larynx; and its sensibility is very evident, when it is pinched or irritated during experiments upon it. On the other hand, the motor character of the inferior laryngeal branch is shown by its very slight sensibility to injury, by its nearly exclusive distribution to muscles, and by its influence in exciting contraction of these when its separated trunk is stimulated.

276. The sensory branch of the vagus supplying the larynx possesses special attributes, which are comparable with those of the inhibitory nerves of the heart, for if moderate excitation be applied to the superior laryngeal nerve, the inspiratory movements are diminished in extent and frequency, whilst if the excitation be more energetic, arrest of respiration with some contraction of the expiratory muscles is produced (Breuer).‖ Similar effects are stated to be produced by stimulation of the inferior laryngeal nerve (Breuer) which must also be regarded as an inhibitory nerve for the respiratory movements. The superior laryngeal nerve responds much more readily to stimuli than the inferior. An inhibitory influence may also be exerted by stimulation of the nostrils—nasal branch of the infra-orbital (Schiff and Kratschmer.¶) Slight irritation of any sensory nerve augments the number of the respiratory movements (Schiff). Strong irritation diminishes (Mantegazza) or altogether arrests them, especially if the excitant be heat, when inspiration-tetanus is produced (Schiff). According to M. Bert** the arrest in the above instances may take place either in expiration or in inspiration, though it is more easily produced in expiration; coincidently with the arrest of the movements of

respiration the general movements of the animal are arrested—it remains perfectly motionless.*

277. There can be no doubt, then, that the superior and inferior laryngeal branches constitute the circle of incident and motor nerves, by which the aperture of the glottis is governed, and by which any irritation of the larynx is made to close the passage, so as to prevent the entrance of improper substances; whilst the superior laryngeal nerve also excites the muscles of expiration, so as to cause the violent ejection of a blast of air, by which the offending gas, fluid, or solid may be carried off. The effect of carbonic acid in causing spasmodic closure of the glottis is well known, and affords a beautiful example of the protective office of this system of nerves.—The mucous surface of the trachea and bronchi appears, from the experiments of Valentin, to be endowed with excitability, so that stimuli applied to it produce expiratory movements; and this evidently operates through the branches of the pneumogastric distributed upon the membrane. Here, as elsewhere, we find that a stimulus applied to the *surface* has a much more decided influence than the irritation of the *trunk* of the nerve supplying it.

278. The importance of moderate excitation of the general sensory nerves of the surface, and especially of the fifth pair, in exciting respiratory movements, is easily shown. Thus, Pflüger† observed that, on opening the abdomen and uterus of a pregnant rabbit at the full time, the fœtuses were brought into view enveloped in the membranes, and quiescent. On detaching the placenta a few feeble inspiratory movements occurred, especially when the animals were pinched; but death soon took place. When, however, the membranes were laid open, lively inspiratory movements followed, which soon became rhythmical. In the same way it has long been a well-known fact that the first inspiratory effort of the new-born infant is most vigorously performed when the cool external air comes into contact with the face; and that impressions on the general surface, such as a slap of the hand on the nates, are often effectual in exciting the first inspiratory movements, when they would not otherwise commence. Dr. M. Hall has mentioned the important fact, that although, if the cerebrum be removed, and the pneumogastrics be divided, in a young kitten, the number of acts of respiration will be reduced to four in a minute, yet by directing a stream of air on the animal, or by irritating various parts of the general surface, we may excite twenty or thirty acts of respiration within the same space of time. He further remarks that in the very young warm-blooded animal, as in the cold-blooded animal, the phenomena of the excito-motor power are far more vividly manifested than in the older and warm-blooded. In the very young kitten, even when asphyxiated to insensibility, every touch, contact, or slight blow, every jar of the table, any sudden impression of the external air, or that of a few drops of cold water, induces at once energetic reflex movements and acts of inspiration. This may be looked upon as Nature's provision for the first establishment of the respiratory function in the new-born animal.‡—But the influence of the nerves of the general system is by no means wanting in the adult, as many familiar facts demonstrate. Thus, every one knows that the first plunge into cold water, or the first descent of the streams of the shower-bath, or even the dashing of a glass of cold water in the face, will produce inspiratory efforts;

* For a full account of the movements of respiration in the frog, with references to the observations of preceding writers, see H. N. Martin, "Journal of Physiology," vol. i. pp. 131 and 170, 1878–79, the latter paper written in conjunction with Dr. Booker.

† Pflüger's "Archiv," 1868, p. 61.

‡ Bernstein observes that prior to birth the thorax is in the extreme condition of contraction, and that the first act of inspiration is due to the elasticity of the walls of this cavity. Pflüger's "Archiv," 1878, Band xvii. p. 617.

and this fact has many important practical applications. Thus, in the treatment of Asphyxia, whether congenital or the result of narcotic poisoning, drowning, &c., the alternate application of cold and heat is found to be one of the most efficacious means of restoring the respiratory movements; and a paroxysm of hysteric laughter may be cut short by dashing a glass of cold water in the face. It seems not improbable that even the sympathetic nerve, which derives many fibres from the cerebro-spinal system, and which especially communicates with the pneumogastric nerves, may be one of the excitors to this function; and this perhaps not only through its ramifications in the lungs, which are considerable, but also by its distribution on the systemic vessels; so that it may convey to the spinal cord the impression of imperfectly arterialised blood through these, such as the pneumogastric is believed to transmit from the lungs.

279. The motor or "efferent" nerves concerned in the function of Respiration are those which Sir C. Bell grouped together in his "respiratory system." The most important of these, the Phrenics, arise from the upper part of the Spinal Cord; the Intercostals much lower down; whilst the Facial Nerve and the Spinal Accessory, to the latter of which, as will be shown hereafter (CHAP. XIII. SECT. 2), the motor powers of the Pneumogastric are chiefly due, take their origin in the Medulla Oblongata itself. M. Brown-Séquard* has paid particular attention to the feeble rhythmical movements of the Diaphragm in Rabbits, which are observed to occur after section of the phrenic nerves, and even after destruction of the entire spinal cord. He attributes them to the minute ganglia described by Rouget, which are found on the filaments of the Phrenic nerve. It is very remarkable that after such serious injury to the nervous system the two sides of the diaphragm, which are chiefly connected by tendon, should act synchronously; and also that the inspiratory movements of the Diaphragm should regularly alternate with those of the expiratory muscles, which in Rabbits are chiefly the external oblique muscles of the abdomen.

280. The actions of *sighing*, *yawning*, *sobbing*, *laughing*, *coughing*, and *sneezing* are nothing else than simple modifications of the ordinary movements of respiration, excited either by mental emotions, or by some stimulus originating in the respiratory organs themselves.—*Sighing* is nothing more than a very slow and long-drawn inspiration, in which a larger quantity of air than usual is made to enter the lungs, followed by a rapid and noisy forced expiration. This is continually taking place to a moderate degree; and we notice it particularly when the attention is released, after having been fixed upon an object which has excited it strongly, and which has prevented our feeling the insufficiency of the ordinary movements of respiration. Hence this action is only occasionally connected with mental emotion.—*Yawning* is a still deeper and longer inspiration, which is accompanied by a kind of spasmodic contraction of the depressors of the lower jaw, and also by a very great elevation of the ribs, in which the scapulæ partake. The purely involuntary character of this movement is sometimes seen, in a remarkable manner in cases of palsy; in which the patient cannot raise his shoulder by an effort of the will, but does so in the act of yawning. Nevertheless this act may be performed by the will, though not completely; and is one that is particularly excited by an involuntary tendency to imitation, as every one must have experienced who has ever been in company with a set of yawners.—*Sobbing* is the consequence of a series of short convulsive contractions of the diaphragm; and it is usually accompanied by a closure of the glottis, so that no air really enters.—

* Brown-Séquard, "Journal de la Physiologie," t. ii. p. 115.

In *Hiccup*, the same convulsive respiratory movement occurs, and the glottis closes suddenly, but later than in sobbing, in the midst of it; the sound is occasioned by the impulse of the column of air in motion against the glottis.—In *Laughing*, a precisely reverse action takes places; the muscles of expiration are in convulsive movement, more or less violent, and send out the breath in a series of jerks, the glottis being open. This sometimes goes on until the diaphragm is more arched, and the chest is more completely emptied of air, than it could be by an ordinary movement of expiration.—The act of *Crying*, though occasioned by a contrary emotion, is, so far as the respiration is concerned, very nearly the same as the last. Every one knows the effect of mixed emotions, in producing an expression of them which is "between a laugh and a cry."—The greater part of the preceding movements seem to belong as much to the *consensual* or to the *emotional*, as to the *excito-motor* group of actions; for, whilst they are sometimes the result of peculiar states of the respiratory organs, or of the bodily system in general, they may also be called forth by influences which operate directly through the senses, or which excite the emotions. Thus, whilst Sighing and Yawning often occur as simple results of deficient aëration, they may be brought on—the former by a depressed state of the feelings, the latter by the mere sight of the act in another person. Laughing is a jerking interrupted expiration, or series of expirations, during which the mouth and glottis remain open, and so the vocal chords are thrown into vibration, giving rise to the well-known sounds. There are at the same time facial expressions. The epiglottis also remains raised, and so the passage of foreign bodies into the larynx is facilitated. Sneezing may be provoked by sudden exposure of the eyes to bright light. Snoring consists in the vibration of the thoroughly-relaxed soft palate induced by the strong influx of air through the nose, or more frequently through the wide-open mouth. The actions of Laughter and Crying seem never to originate in the respiratory system; but to be always either expressions of the emotions, or simple results of sensations—as when crying arises from the sense of pain, and laughter from that of tickling. The origin of the act of Hiccup does not seem very clear; but the movement is probably of a purely reflex nature.

281. The purposes of the acts of Coughing and Sneezing are, in both instances, to expel substances from the air-passages, which are sources of irritation there; and this is accomplished in both by a violent expiratory effort, which sends forth a blast of air from the lungs.—*Coughing* occurs when the source of irritation is situated at the back of the mouth, in the glottis, trachea, or bronchial tubes. The irritation may be produced by acrid vapours, or by liquids or solids, that have found their way into these passages; or by secretions which have been poured into them in unusual quantity, as the result of disease; or by the simple entrance of air (especially if cold), when the membrane is in a peculiarly irritable state. Any of these causes may produce an impression upon the excitor fibres of the superior* and inferior† laryngeal branches of the Pneumogastrics, which, being conveyed to the Medulla Oblongata, gives rise to the transmission of a motor impulse to the several muscles, that combines them in an act of expiration. The act of coughing consists—1st, in a long inspiration, which fills the lungs; 2nd, in the closure of the glottis and of the larynx at its upper orifice by the approximation of the epiglottis to the walls of the pharynx (Ed. Smith) at the moment when expiration commences; and, 3rd, in the bursting open (as it

* See Rosenthal, "Die Athembewegungen," 1862; and Reichert's "Archiv," 1844.
† Burkart, Pflüger's "Archiv," Band i. p. 107.

were) of the glottis, by the violence of the expiratory movement; so that a sudden blast of air is forced up the air-passages, carrying before it anything that may offer an obstruction.—The difference between Coughing and *Sneezing* consists in this—that in the latter, the communication between the larynx and the mouth is partly or entirely closed by the drawing together of the sides of the velum palati over the back of the tongue; so that the blast of air is directed more or less completely through the nose, in such a way as to carry off any source of irritation that may be present there.—It is difficult to say how far these actions are independent of consciousness, or how far they may require the stimulus of sensation for their performance.

282. Various alterations are produced in the Lungs by section of the Pneumogastric nerves; the inquiry into the nature and succession of which were most carefully prosecuted by Dr. J. Reid;* who fully established that section of the Vagus on *one* side only does not necessarily, or even generally, induce disease of that lung; and hence the important inference may be drawn that the nerve does not exercise any *immediate* influence on its functions. When *both* Vagi are divided, however, the animal rarely survives long; but its death frequently results from the disorder of the digestive functions. Nevertheless, the power of digestion is sometimes restored sufficiently to re-invigorate the animals; and their lives may then be prolonged for a considerable time (§ 92). Some remarkable effects were observed by Dr. Reid in the Lungs of Mammals, after section of both pneumogastric nerves. This operation, in general, proves rapidly fatal, and, after death, the blood-vessels of the lungs are found to be intensely congested, a condition of broncho-pneumonia being established. Dr. Reid regarded the congestion of the blood-vessels as the first departure from the healthy state of the lung; and Schiff,† taking the same view, explained the congestion as a condition of neuro-paralytic hyperæmia, due to paralysis of vasomotor nerves which he supposed to run in the trunk of the pneumogastric nerves. Various observers, however,‡ pointed out that the inflammation might really arise from the entrance of particles of food or other foreign bodies into the larynx, which the animal was no longer able to prevent on account of the loss of sensibility of the parts supplied by the superior laryngeal nerve. This view is supported by the fact, when this has been prevented by keeping the animal on its back, and thus avoiding the entrance of saliva or food, no pneumonia occurred,§ whilst section of the recurrents alone, which paralysed the larynx, was followed by the pneumonia. When death does not result from pneumonia or asphyxia, due to collapse of the flaccid borders of the laryngeal opening, it seems to be the consequence, in birds, of fatty degeneration of the muscular fibres of the heart, or of some analogous change in mammals.‖

2. *Effects of Respiration on the Air.*

283. The total amount of air which can be drawn into the Lungs by the deepest possible inspiratory movement by no means affords a measure of the quantity which they ordinarily contain. It is in fact composed, as was first pointed out by Mr. Julius Jeffreys,¶ of several different quantities, which may be distinguished as follows:—

* Op. cit.

¶ "Statics of the Human Chest," 1843.

1. *Residual Air:* that which cannot be displaced by the most powerful expiration, which always remains in the thorax so long as the lungs retain their natural structure, and over which, therefore, we have no control.

2. *Supplemental Air:* that portion which remains in the chest after the ordinary gentle expiration, but which may be displaced at will.

3. *Breathing* or *Tidal Air:* that volume which is displaced by the constant gentle inspiration and expiration.

4. *Complemental Air:* the quantity which can be inhaled by the deepest possible inspiration, over and above that which is introduced in ordinary breathing.—The amount which can be expelled by the most forcible expiration after the fullest inspiration, and which is consequently the sum of the supplemental tidal and complemental air, is designated by Dr. Hutchinson* as the *Vital Capacity*, being that volume of air which can be displaced by *living movements*. This "vital capacity" is less dependent than might have been supposed upon the absolute *dimensions* of the thoracic cavity, being yet more influenced by its *mobility*. Thus, of two sets of men of the same height, one measuring 35 inches round the chest, and the other 38 inches, the average vital capacity of the first was found to be 235 inches, and that of the second only 226 inches; for, notwithstanding the greater absolute capacity indicated by the larger circumference of the latter, the inferior mobility of the chest caused more "residual air" to remain behind after the deepest expiration. By taking the average of nearly 5000 observations, Dr. Hutchinson has arrived at the very remarkable conclusion,† that of all the elements whose variation might be supposed to affect the "vital capacity," *Height* alone seems to have any constant relation to it; and that this relation is capable of being expressed in a simple numerical form. It may be briefly expressed by the rule, that *for every inch of stature, from five to six feet, eight additional cubic inches of air* (60° Fahr.) *are given out by a forced expiration after a full inspiration:* the vital capacity for a man from 5 feet to 5 feet 1 inch being 174 cubic inches; from 5 feet 1 inch to 5 feet 2 inches, 182 cubic inches, and so on.‡—There is also a relation between "vital capacity" and *Weight;* but of a different kind from that which might have been anticipated. So far as the increase in weight is simply proportional to the increase in height, the relation is, of course, the same for the one as for the other. But if the excess of weight should depend upon corpulence, the vital capacity *decreases* in a very marked manner, being always very low in corpulent men. The general result of Dr. Hutchinson's observations on this point is expressed by him as follows:—When the man exceeds the average weight (at each height) by 7 per cent., *the vital capacity decreases* 1 *cubic inch per lb. for the next* 35*lbs. above this weight.*—The influence of *Age* upon the "vital capacity" is less marked than might have been anticipated. The general fact seems to be, that the "vital capacity" undergoes a slight increase between fifteen and thirty-five years, and then gradually decreases, the decline being more rapid than the augmentation, so that by the age of sixty-six it has diminished to about 4-5ths of the maximum.—There does not seem to be as close a relation between the "vital capacity" and *Muscular Vigour* as might *à priori* have been expected, and as an attempt has been made to establish.§ Cases are not unfrequent in which men of athletic constitution have an absolute deficiency, whilst others,

* "Cyclop. of Anat. and Physiol.," vol. iv., Art. 'Thorax.' † Op. cit., p. 1072.

‡ For similar results obtained by an ingenious method suggested by M. Gréhant see "Med.-Chir. Rev.," 'Report on Physiology,' Jan. 1865, p. 231. The average vital capacity of Englishmen is given by Landois at 3772 C. cmts., and of Germans by Haeser at 3222 C. cmts.

§ See Dr. Jackson in "American Medical Examiner," 1851, p. 51.

by no means remarkable for physical power, present a large excess.* In fact, as Dr. C. R. Hall has justly remarked, this measure indicates, not what a person *does* breathe, but what he *can* breathe.—The *maximum* "vital capacity" met with by Dr. Hutchinson in his entire series of observations was 464 cub. in.; this was in a man 7 feet high, whose weight was 308 lbs. The *minimum* was no more than 46 cub. in.; this was in a dwarf (Don Francisco) whose height was only 29 inches, and weight 40 lbs. It is considered by Dr. Hutchinson† that a deficiency of 16 per cent. (unless the individual should be very corpulent) should excite suspicion of disease; but the observations of Dr. C. R. Hall (loc. sit.) seem to show that the range is considerably wider, especially in females. The vital capacity diminishes when the pressure of the air is quickly reduced, as in ascending a mountain, but after a few days' exposure to the reduced pressure the vital capacity is re-established.‡

284. In estimating, however, the effects of the Respiratory function upon the air which passes through the lungs, we are not so much concerned with the quantity which *may* be drawn in and forced out, as with that actually exchanged at each movement. The estimates of the earlier observers, Herbst, Valentin,§ &c., which ranged from 10 to 92 cub. in., are in general imperfect, having been based upon comparatively few respirations, and without taking into consideration the many circumstances we now know to exercise an influence upon the depth and frequency of the respiratory acts. Dr. Ed. Smith‖ has arranged a spirometer, by which the quantity of air inspired may be registered from 1 to 1,000,000 cub. in., and therefore for any period. He has used it for 24 hours without intermission, except for meals, and ascertained the quantity of air inspired during sleep, and in almost every condition met with during the day. From numerous experiments upon several persons, each extending over a whole day, he found that the average depth of inspiration was 33·6 cub. in. when at rest, and when walking at 1, 2, 3, and 4 miles per hour, 52, 60, 75, and 91 cub. in., and even 107 cub. in. when working the treadmill. If we take 30 or 40 cubic inches as the average quantity exchanged at each respiration, we cannot but observe how small a proportion it bears to the entire amount which the lungs usually contain; for the "residual air," which cannot be expelled, is estimated by Dr. Hutchinson at from 75 to 100 cubic inches, and the "supplemental air," which can only be expelled by a forced expiration, is about as much more; the sum of the two being from 150 to 200 cub. in., or from 5 to 7 times the "breathing volume."

* See Dr. C. Radclyffe Hall in "Trans. of Prov. Med. and Surg. Assoc.," 1851.

† Op. cit., p. 1079.

‡ See Rattray, "Proceed. Roy. Soc.," 1870, p. 513, 1872, p. 2, and F. Cresswell Hewett, "Brit. Med. Journ.," vol. ii. 1875, p. 667. In Mr. Hewett's experiments on two officers who climbed Madeira, 2950 feet, the reduction of vital capacity on the first day after the ascent was about 23 cub. inches, and the normal amount was reached in three days. He explains it by the hypothesis that the lungs become accommodated through hyperæmia to the diminished pressure, but it might also be explained by admitting fatigue of the muscles effecting forced inspiration.

§ The following are some of the amounts assigned by different observers:—

Herbst		20—30 cubic inches.
Valentin		14—92 ,,
Vierordt		10—42 ,,
Coathupe		16 ,,
Hutchinson	average	16—20 ,,
	extreme	7—77 ,,
Gréhant		0·510 of a litre.

(Gréhant, Robin's "Journal de l'Anatomie," t. i. p. 523.)

‖ Many of the following statements respecting Dr. Edward Smith's experiments were kindly communicated by himself.

Now, it is obvious that if no provision existed for mingling the air inspired with the air already occupying the lungs, the former would penetrate no further than the larger air-passages; and as this would be again thrown out at the next expiration, the bulk of the air contained in the lungs would remain altogether without renewal, and the expired air would not be found to have undergone any change.* That a change *is* effected, however, in the whole volume of the air contained in the lungs, with every inspiration, is indicated by the difference between the inspired and expired air; and its amount has been ascertained by Gréhant by means of his method, in which hydrogen gas is inspired, to be that about two-thirds of the pure air inspired remains in the lung, whilst the other third is expelled mingled with two-thirds of vitiated air.†

285. The *total amount* of air which passes through the lungs in twenty-four hours will, of course, vary with the extent and frequency of the respiratory movements; and these are liable to be affected by many circumstances, but particularly by the relative degrees of repose and of exertion. Moreover, as any such computation must be based upon the datum of the ordinary volume of breathing or "tidal" air, it is obvious that the estimates of different observers must vary with the amount they adopt. Dr. Ed. Smith found that during the day (6 A.M. to 12 night) the average quantity of air inspired by several persons at rest was 502 cub. in. per minute, or a total of 542,160 cub. in. (nearly 314 cub. feet); and as the average quantity during the night was about 400 cub. in. per minute, the total daily amount was 686,000 cub. in. (397 cub. feet), which is in close approximation to the results of Valentin, who estimated the total daily amount at 688,348 cub. in. The quantity is largely increased by exertion, and Dr. Smith computes that the total amount actually respired by the unoccupied gentleman, the ordinary tradesman, and the hard-working labourer, would be 804,780 cub. in., 1,065,840 cub. in., and 1,568,390 cub. in.; and with 12 hours of Alpine walking, as over the Wengern Alp, 1,764,000 cub. in. (1020 cub. feet). When carrying weights, as by the soldier in his heavy marching order, Dr. Smith found an increase of 7 cub. in. per minute for every 1 lb. weight carried.

286. The *alterations* in the Air‡ which are effected by Respiration, consist

* See Mr. Jeffreys' "Statics of the Human Chest," in which this important point first received due consideration.

† See for an account of his method, Budge, "Compendium de Physiologie," trad. par Eugène Vincent, 1874, p. 78.

‡ The volumetric composition of ordinary atmospheric air in England is thus given by Dr. Miller ("Elements of Chemistry," vol. ii. p. 455):—

Oxygen	20·61	Nitric Acid, Ammonia, and Carburetted Hydrogen	traces.
Nitrogen	77·95		
Carbonic Acid	0·04	And in towns—Sulphuretted Hydrogen and Sulphurous Acid.	traces.
Aqueous Vapour	1·40		

The composition by weight of pure dry air is O. 23·015, N. 76·985. When fully saturated, air at 50° F. is stated by Pettenkofer to contain about 4 grains of water per cubic foot, at 60° F. it contains about 7. The average hygrometric condition of the atmosphere at 50° F. is such that it contains about 3 grains per cubic foot, or about 75 per cent. of its full saturation. At the ordinary temperature of the month of July, the atmosphere is capable of containing nearly three times as much aqueous vapour as in December; nevertheless, the quantity of moisture actually present is generally greater in winter, owing to the greater rainfall. In air blowing over a wide expanse of sea, and after thunderstorms, a certain portion of the oxygen appears to possess the properties of ozone. Its presence is recognised by its power of decomposing potassium iodide, and causing paper dipped in a solution of this salt and starch-paste to turn blue, but no means are known of determining its quantity. Ozone disappears in air that has blown over even a narrow belt of houses, as was shown many years ago by Faraday at Brighton, and is rarely present in the air of rooms. Its action is not known, though it is generally considered to be stimulating and invigorating, and Schönbein regards it as the cause of catarrhal affections.

in its saturation with aqueous vapour, the elevation of its temperature to 97°·6 Fahr.,* and in the removal of a portion of its *oxygen*, and the substitution of a quantity of *carbonic acid* usually rather less in bulk than the oxygen which has disappeared. Very small quantities of Ammonia, of Light Carburetted Hydrogen, of Hydrogen and Nitrogen, with some volatile organic compounds which communicate an odour to the breath, are also eliminated by the lungs. Probably about 4·38 per cent. may be taken as the average amount of Carbonic acid added to the air, at the ordinary rate of respiration; whilst, according to Vierordt, the amount of oxygen removed is 4·782 per cent.; the absolute diminution in bulk of the expired air, when deprived of the moisture which it has acquired in passing through the lungs, being from 1-40th to 1-50th of its volume (1 : ·906), though its weight, owing to the sp. gr. of carbonic acid being greater than that of oxygen, is rather increased. Supposing the entire amount of air respired per diem to be 1,000,000 c. i., or 578 cubic feet, or 3600 gallons, as given by Dr. Smith for an ordinary tradesman, the absolute quantity of oxygen withdrawn from the air in the respiratory acts may be estimated at about 5000 cubic inches, or 30 c. ft. (= 5 per cent.); the weight of which would be about 18,000 grains, or rather more than $2\frac{1}{2}$ lbs. avoirdupois (Vierordt estimates it at 11,484 grains = 516,500 C. cmtr.). A curious calculation has been made by Welcker, to the effect that the surface presented for aëration, by the entire mass of the red corpuscles of the blood, amounts to no less than 2816 square metres, or estimating the amount propelled through the lung in each second to be 176 cubic centimetres, the surface presented by the corpuscles contained in that quantity of blood would amount to 87 square metres, or a square of 13 military steps to the side. It is deserving of notice in regard to the elimination of Carbonic acid, that if the air be already charged to some extent with this gas, the quantity exhaled is much diminished (Allen and Pepys).

287. The absolute quantity of Carbonic acid exhaled from the Lungs is liable to variation from so many sources that no fixed standard can be assigned for it. The mean of a great number of observations, however, made in different modes and under different circumstances, would give about 160 grains of Carbon per hour as the amount set free by a well-grown adult man, under ordinary circumstances. Taking this as the average of the twenty-four hours, the total quantity of Carbon thus daily expired from the Lungs would be 3840 grains, or 8 oz. troy, which is equal to 14,080 grains of Carbonic acid.† Vierordt gives a lower estimate—viz., 13,889 grains = 455,500 C. cmtr. at 0° C. and mean pressure. According to Dr. Edward Smith, who has devised an apparatus by which all the Carbonic acid exhaled may be collected for a whole day without intermission except for food, the total amount evolved in 24 hours at rest (deduced from experiments on different persons) was 7·144 ozs. of Carbon; and he estimates that it should be increased to 8·68 ozs. and 11·7 ozs. for the non-labouring and laborious classes respectively, at their ordinary rate of exertion. The chief causes of variation are—the Temperature and Hygrometric state of the surrounding Medium, Age, Sex, Development of the Body, Nature and Quantity of Food and state of the Digestive process, Muscular Exertion or Repose, Sleep or Watchfulness, Period of the Day, Season, and state of Health or Disease. These will now be considered in detail :—

* Weyrich, "Observations on the Insensible Perspiration of the Lungs and Skin," 1865. The temperature of the expired air varies to some extent with the temperature of the air inspired. Thus air inspired at 20° F. only rises to 85°·5, whilst air inspired at 106° is expired at 100°·5 F.

† Scharling estimated the hourly elimination of Carbonic Acid to be on the average 36 grammes, or 556 grains, and by Panum it is given as 34 grammes, or 525 grains.

I. *Temperature of surrounding Medium.*—The amount of Carbonic acid exhaled by warm-blooded animals is greatly *increased* by external *Cold*, and *diminished* by *Heat*. From Letellier's* experiments it appears that the quantity of Carbonic acid exhaled by Mammals between 86° and 106° is less than *half* that set-free near the freezing point; whilst that which is exhaled between 59° and 68° is but little more than *two-thirds* of the same amount. The diminution occasioned by heat is still more remarkable in Birds; which exhale at the highest temperature scarcely more than *one-third* of that set-free at the lowest.—The observations of Vierordt† upon himself show that the same is true of the human subject; and a difference of 10° Fahr., according to him, produces a variation of rather more than two cubic inches in the amount of Carbonic acid hourly expired. Dr. Ed. Smith found that sudden increase of temperature occasioned sudden decrease, in an increasing ratio, in the quantity of Carbonic acid evolved, amounting to 1·3 grain per minute for 16° Fahr. of temperature; but that in experiments continued over long periods there was the greatest diversity in the proportion of Carbonic acid evolved to each degree of temperature.

II. That the *Hygrometric state of the Air* influences the rate of exhalation of Carbonic acid appears from some experiments by Lehmann made with this express view. For he found that while 1000 grammes' weight of Pigeons yielded, in *dry* air, 6·055 grammes of Carbonic acid per hour, at the temperature of 75°, and 4·69 grammes at the temperature of 100°, the same animals, in *moist* air, yielded 6·769 grammes at 73°, and 7·76 grammes at 100°. And while 1000 grammes' weight of Rabbits exhaled, in *dry* air, 0·451 gramme per hour, at a temperature of 100°, they exhaled as much as 0·677 gramme in a *moist* atmosphere at the same temperature.‡

III. The amount of Carbonic acid exhaled increases in both sexes up to about the thirtieth year; it remains stationary until about the forty-fifth; and then it diminishes. Thus, according to Andral and Gavarret,§ at 8 years of age, 77 grains of carbon are excreted per hour; at 14 years, 126 grains; at 20 years, 166 grains; at 48 years, 162 grains; and at 76 years, 92·4 grains.

IV. *Sex.*—At all ages beyond eight years, the exhalation is greater in Males than in Females. Nearly the same proportionate increase takes place, however, in Females, up to the time of puberty; when the quantity abruptly ceases to increase, and remains stationary so long as they continue to menstruate. When, however, menstruation has ceased, the exhalation of Carbonic acid begins again to augment; and then again diminishes, with the advance of years, as in men. Should menstruation temporarily cease at any time, the exhalation of Carbonic acid immediately undergoes an increase, precisely as at the final cessation of the function. During pregnancy, the exhalation increases in like manner.

V. *Development of the Body.*—The more robust the individual, *cæteris paribus*, the more Carbonic acid is exhaled; and the variation is much more influenced by the development of the muscular system, than by the height or weight, capacity of the chest, &c. Thus, a very strong man of twenty-six years of age exhaled at the rate of 217·1 grains of carbon per hour; while a man of moderate muscular power set-free but 169·4 grains in the same time. Another robust man of sixty years of age exhaled at the rate of 209·4 per hour; and an old man of ninety-two years, who still preserved an uncommon degree of

† "Physiologie des Athmens," pp. 73–82.

‡ Lehmann, Op. cit., Band iii. p. 304.

§ "Annales de Chimie et de Physique," 1843.

energy, and who in his younger days had boasted of extraordinary muscular powers, exhaled at the rate of 135·5 grains per hour. So, also, a remarkably vigorous young woman of nineteen years exhaled at the rate of 107·8 grains per hour; and a strong woman of forty-five years (who had ceased to menstruate), 152·4 grains.—On the other hand, a slender man of forty-five years, in the enjoyment of good health, only exhaled at the rate of 132·4 grains per hour (Andral and Gavarret). In Dr. Ed. Smith's experiments the quantity of *carbon* expired per diem to each 1 lb. of body-weight was 17·07 grains, 17·51, and 17·99, at 48, 39, and 33 years of age respectively.

VI. *Nature and Quantity of the Food and State of the Digestive Process.*—It is well established that the exhalation of Carbonic acid is greatly increased by eating, and that it is diminished by fasting. Thus, Prof. Scharling states the hourly exhalation to have increased in one instance from 145 to 190, after breakfast and a walk; in another from 140 to 177, after breakfast alone; and in another from 111·9 to 188·9, after dinner. Dr. Ed. Smith on several occasions fasted for more than twenty-four hours, and collected all the Carbonic acid exhaled during the whole period, or during ten minutes at each hour of the waking day. He found the total daily amount of carbon exhaled at rest and whilst fasting to be 5·923 ozs.; and there was scarcely any variation in the hourly quantity during the hours of the day. He noticed that there was a line below which the quantity of Carbonic acid did not fall, during waking hours in health; this, which he has termed the *basal line*, is that observed at rest and in the absence of food. The increase above that line, which is caused by food, seldom exceeds one-half of the basal quantity, or about 3 grains per minute. He has shown that the increase is from 2 to 3 grains per minute after breakfast and tea, and from 1 to 2 grains per minute after early dinner, whilst he scarcely found any increase after supper. He has examined the influence of numerous foods, as flesh, fish, albumen, gelatin, bread, rice, oatmeal, cane, grape, and milk sugar, milk, tea, coffee, cocoa, starch, gluten, butter, olive oil, alcohol, rum, gin, brandy, sherry and port wine, beer and spirits. All nitrogenous foods—gluten, casein, flesh, fish, albumen and gelatin—increased the evolution of Carbonic acid to the extent of $\frac{3}{4}$ to 1 grain per minute; but tea, coffee, bread, rice, oatmeal, milk, and sugar increased it from $1\frac{1}{2}$ to 3 grains per minute. Fats and starch did not increase it; alcohol, rum, and ales increased it from $\frac{1}{2}$ a grain to 2 grains per minute, whilst brandy and gin decreased it, and 3 ounces of wine exerted but little influence. The inhalation of the aroma of wines decreased it. All Dr. Smith's experiments were made in the sitting posture, at rest, before breakfast, and upon one substance alone in moderate quantity, the dose of which was repeated every ten or fifteen minutes, until the maximum influence had been obtained. With sugar, alcoholic liquids, tea, coffee, the maximum influence was observed in from twenty to thirty minutes; but with bread, oatmeal, milk, and flesh, it was commonly later, and continued from $1\frac{1}{2}$ to $2\frac{1}{2}$ hours. With sugar and tea there was frequently an increase of 1 grain per minute in less than ten minutes. The whole of the Carbonic acid exhaled during five minutes at a time for two hours was collected and weighed; the per-centage was not sought for. Dr. Smith has called attention to the separate action of the alcohol, aromas, sugars, and nitrogenous matters in each of the alcoholic compounds.*

* Similar though less extended and perfect observations have been made by Vierordt, Bidder, Schmidt, Pettenkofer and Voit, and Perrin ("Comptes Rendus," 1864, p. 257). See also Speck, "Centralblatt f. d. Med. Wiss.," 1876, p. 289, who finds that the greater the excess of C over H in the food, the larger is the quantity of CO_2 excreted, and the larger the

VII. *Muscular Exertion or Repose.*—The effect of bodily exercise, in moderation, is to produce a considerable increase in the amount of Carbonic acid exhaled, both during its continuance and for some little time subsequently to its cessation. According to the observations of Vierordt, the increase amounts to one-third of the quantity exhaled during rest, and it lasts for more than an hour afterwards; being manifested in the greater quantity of air respired, and in the larger per-centage of Carbonic acid contained in it. If the exercise be prolonged, however, so as to occasion fatigue, it is succeeded by a diminished exhalation.—Dr. Ed. Smith found that whilst walking at two and three miles per hour, the quantity of Carbonic acid evolved was 18·1 grains and 25·83 grains per minute, which are respectively 1·85 and 2·64 times more than that eliminated in the quiet sitting posture. With treadwheel labour the quantity varied from 42·9 grains to 48·66 grains. After the exertion had ceased, the increase continued for some time; and not the least exertion could be made, even when sitting, without disturbing the results.—In the experiments of Pettenkofer and Voit* the following results were obtained in the case of a healthy man, æt. 28, weighing 132 lbs., fed on ordinary diet, engaged in reading and cleaning watches, and extending over twenty-four hours:—

Period of the day.	Elimination of CO_2 through Lungs in grains.	Elimination of H_2O through Skin and Lungs in grains.	Amount of Oxygen absorbed.	Per-centage of the inspired Oxygen in the Carbonic Acid.
Day.				
6 A.M.—6 P.M. .	826·0	533·8	363·6	271·2
Night.				
6 P.M.—6 A.M. .	586·8	749·8	735·1	89·9
Total in 24 hours.	1412·8	1283·6	1098·7	361·1

A few days later the same man worked till exhausted.

Day	1371·1	169·69	456·9	337·9
Night	619·4	146·83	1022·5	68·2
Total	1990·5	316·52	1479·4	406·1

The connection between muscular exertion and the exhalation of Carbonic acid is most remarkably shown in Insects; in which animals we may witness the rapid transition between the opposite conditions of extreme muscular exertion and tranquil repose; and in which the effects of these upon the respiratory process are not masked by that exhalation of Carbonic acid which is required in warm-blooded animals simply for the maintenance of a fixed temperature. Thus, a Humble-Bee was found by Mr. Newport† to produce one-third of a cubic inch of Carbonic acid in the course of a single hour, during which its whole body was in a state of constant movement, from the excitement resulting from its capture; and yet, during the whole twenty-four hours of the succeeding day, which it passed in a state of comparative rest, the quantity of Carbonic acid generated by it was absolutely less.

VIII. *Sleep or Watchfulness.*—The amount of Carbonic acid exhaled during sleep is considerably less than that set free in the waking state. This is par-

quantity of O absorbed; whilst the larger the amount of H contained in the food, the smaller is the quantity of O absorbed, statements that generally corroborate the conclusions drawn by Dr. E. Smith.

* "Münchener Akad. Berichte," 1867, No. 10. † "Philos. Transact.," 1836.

icularly shown by the experiments of Scharling;* who confined the subjects of them in an air-tight chamber, within which they could sleep, take their meals, &c. Thus, in one case the hourly exhalation sank from 160 to 100, in another from 194·7 to 122·3, and in another from 99 to 75·1. With customary food and exercise Pettenkofer and Voit in one experiment found that of the total amount of Carbonic acid eliminated during 24 hours, 58 per cent. was given off during the twelve hours of the day, and 42 per cent. during the 12 hours of the night; whilst 33 per cent. of the oxygen was taken up by day, and 67 by night. Dr. Ed. Smith found that 4·88 and 4·99 grs. of Carbonic acid were exhaled per minute during light sleep from 1 to 3 A.M., and he estimates the quantity in profound sleep at $4\frac{1}{2}$ grs. He also observed that 5·7 grs., 5·94 grs., and 6·1 grs. per minute were evolved at 1.30, 2.30, and 6.15 A.M., whilst awake, the average amount during the waking day being 9·77 grs. per minute in the same person. The cause of this result is partly to be sought in the cessation of all muscular exertion (save that concerned in the maintenance of the respiration), and partly in the diminution in the dissipation of the heat of the body itself.

IX. *Period of the Day.*—Independently of these variations, which have their source in the condition of the individual, there is reason to believe that there is a diurnal cycle of change in the quantity of Carbonic acid exhaled; the *maximum* being (*cæteris paribus*) before and after noon, and the *minimum* before and after midnight. From the experiments of Scharling upon the Human subject, it would appear that the average proportion exhaled by day to that exhaled by night is as $1\frac{1}{4}$ to 1; and this difference does not seem to be affected by sleep or wakefulness. Dr. Ed. Smith found that the quantity of Carbonic acid varied at every moment; and that there were similar hourly variations in the quantity of Carbonic acid evolved, as in the rate of pulsations to which we have already referred. There was the least during the middle hours of the night, a slight increase with sunlight, a large increase after the meals, and a decrease before them, and a prolonged and inevitable fall after about 9 o'clock P.M. The proportion in the night of six hours to the day of 18 hours was in himself as 1 : 1·8. Most persons are conscious of a greater difficulty in bearing exposure to cold between midnight and early morning, than at any other period in the twenty-four hours.†

X. *Season.*—Dr. Edward Smith has investigated the influence of season by determining the amount evolved at rest, in the sitting posture, and before breakfast, daily throughout the year, and has found that the greatest amount occurs in April and May; that there is a decrease commencing in June, and continuing progressively through June, July, and August to September; and that in October, November, and December there is an increase. He considers that there is a maximum period (end of Winter and Spring), a minimum period (end of Summer to Autumn), an increasing period (Winter), and a decreasing period (early Summer). The extreme loss at the end of Summer was 3 grains of Carbonic acid per minute, or 33 per cent., and on the monthly average the loss was 17 or 18 per cent. He has applied this to the causation and treatment of disease, and has shown that the influence of the rotation of the seasons is a prime element in the *vis medicatrix naturæ*. Temperature and Barometric pressure to some extent, but very imperfectly, explained the results. A medium temperature was accompanied by the most

* "Ann. der Chem. und Pharm.," 1843; transl. in 'Ann. de Chim. et de Phys.,' 1843.

† Perhaps the smaller quantity of CO_2 exhaled by night than by day is due to less food being taken at this time. See the experiments of Henneberg, E. Schulze, Märker, and Busse on sheep in "Centralblatt f. d. Med. Wiss.," 1870, p. 353.

diverse quantities of Carbonic acid at the different seasons, but extremes exhibited marked influence.

XI. *Frequency of Respiration.*—Vierordt* found that, if he only respired *six* times in a minute, the quantity of Carbonic acid was 5·5 per cent. of the whole air exhaled; with *twelve* respirations, it was 4·2; with *twenty-four*, it was 3·3; with *forty-eight*, it was 3·0; and with *ninety-six*, it was 2·6 per cent. Considerable differences of opinion are held by different observers as to the influence of increased frequency of respiration on the total amount of Carbonic acid. On the whole it is probable that the mechanical variations of respiration have little or no influence on the absolute of Carbonic acid eliminated.† If the breath be held for 40 seconds (Vierordt), or 100 seconds (Stefan), the proportion of Carbonic acid may rise to upwards of 7½ per cent., and if the same air be breathed over and over again the proportion may attain 9 per. cent (Müller, Setschenow).

XII. *State of Health or Disease.*—Upon this very important cause of variation few accurate researches have yet been made. The *per-centage* of Carbonic acid in the expired air has been found to be unusually great in the Exanthemata, and in chronic Skin-diseases (Macgregor);‡ and it has been stated to be diminished in Typhus (Malcolm).§—Thus, the average proportion of health being about 4·3 per cent. (Vierordt), it has been seen at 8 per cent. in confluent Small-pox, at 5 per cent. in Measles, and at 7·2 per cent. in a severe case of Ichthyosis which terminated fatally; whilst in Typhus the per-centage has been found to range from 1·18 to 2·50. But these statements do not indicate the total quantity exhaled in each case.—The remarkable increase of the exhalation in cases of Chlorosis has been already noticed; in four cases recorded by Hannover, the hourly expiration was 123·6, 118·6, 116·9, and 106·3 grains; the absolute quantity diminishing as the respirations increased in rapidity. In chronic diseases of the respiratory organs, as might be anticipated, the amount of Carbonic acid exhaled undergoes a sensible diminution (Nysten‖ and Hannover).¶—Further researches are much needed on this subject; but, for obvious reasons, they cannot be readily made in severe forms of disease.—The greater part of the Oxygen absorbed in respiration is again eliminated in combination with Carbon as Carbonic acid. In the original experiments of Lavoisier on Guinea pigs, 81 per cent. of the Oxygen thus reappeared, the remaining 19 per cent., which disappeared, were believed by him to unite with hydrogen to form water. The results of Regnault and Reiset's experiments on various animals—mammals, birds, reptiles, insects, and annelids**—were almost precisely the same; the general average being, that for each kilogramme of weight of the animal there were absorbed per hour 3·0219 grammes of oxygen; whilst there were exhaled 3·2544 grammes of Carbonic acid; and they found that 80·5 per cent. of the Oxygen absorbed was discharged in combination with the Carbon, but considerable variations occurred connected with the nature of the food, a larger proportion of the Oxygen absorbed being combined with Carbon, when the food was rich in

* "Physiologie des Athmens," pp. 102–149. Panum (Pflüger's "Archiv," Band i.) and Berg ("Archiv f. Klin. Med.," Band vi.) arrived at the same results as Vierordt, but Lossen ("Zeitschrift f. Biologie") thinks that when the respirations are simply increased in number in a given time their greater shallowness compensates for their increased frequency, and no more CO_2 is given off.

† See for a discussion of this point Pflüger, "Pflüger's Archiv," Band xiv. 1877, p. 1; and Lossen, "Zeitschrift für Biologie," Band ii. p. 252.

Carbon,* amounting in Ruminants to about 100 per cent. Pettenkofer and Voit† also found the proportion of Oxygen eliminated in the form of Carbonic acid varied, in a large dog, from 52·4 to 148·2, according as he was kept altogether without food, or was fed upon a mixed diet of meat and sugar.

The Table (p. 372) shows a remarkable excess of the diurnal against the nocturnal elimination of Carbonic acid, especially after work, and a corresponding increase in the per-centage of the absorbed Oxygen which is thus discharged. On the other hand, the absorption of Oxygen appears to take place most energetically during the night, whilst taking the whole period of 24 hours into consideration, it appears that in both sets of experiments from 94 to 98 per cent. of the oxygen absorbed is eliminated in combination with Carbon as Carbonic acid. In other and still more recent researches, the same difference was not observed‡ between the day and night absorption of Oxygen and elimination of Carbonic acid, and no definite statement as to the exact proportion can therefore as yet be made. The elimination of Urea corresponded in its variations to that of the Carbonic acid, being 21·7 grammes by day and 15·5 grammes by night.

288. The effects of exposure to increased atmospheric pressure have been made the subject of experiment by various physiologists,§ but have been best illustrated by the observations made by Dr. Jaminet‖ on himself and on the workmen engaged in the construction of the Illinois and St. Louis Bridge over the Mississippi River. In the course of this work the men were engaged in excavations conducted at a depth of 115 feet below the level of the surface of the river, the pressure of the air then amounting to upwards of fifty pounds on the square inch of their bodies, exclusive of the ordinary atmospheric pressure of fifteen pounds on the square inch. No ill effects were observed, even when the pressure was greatest, whilst the men were working in the air-chambers; it was only on suddenly emerging that great exhaustion, pain in the epigastrium and spine, sickness, paraplegia, involving the bladder and rectum, and even death occurred. Great care was taken that on entering and leaving the air-chambers the workmen should remain for ten minutes or more in lock chambers, in which the pressure of air was gradually increased or diminished. The pulse and respiration usually rose in frequency on exposure to the augmented pressure, and free perspiration occurred; but it must be remembered that the air-chambers were small, and the temperature in them was many degrees above that of the open air. The Urine and Urea were at the same time increased. Speaking generally, there seems to be reason for believing that under the conditions to which the men were here subject, with moderate pressure (20 lbs. to the square inch), the activity of the physiological functions was augmented, though there seemed to be a reaction on return to ordinary pressure. In the cases in which death occurred, the Brain and Spinal cord were found to be highly congested, and their cavities filled with serum. M. Vivenot's experiments showed that an increase of pressure amounting

* Kowalewsky, "Arbeiten aus der Physiol. Anstalt zu Leipzig," 1867, p. 33, was only able to obtain about 50 per cent. of the oxygen absorbed in the carbonic acid exhaled, by means of his new apparatus, in rabbits fed on cabbage leaves.

‖ "Physical Effects of Compressed Air observed in the Construction of the Illinois and St. Louis Bridge, 1871."

to one-fifth of the normal decreased the respiration two, and the pulsations ten per minute; and it may be accepted as a general fact that in compressed air the respirations are diminished in number, but increased in depth, though the increase in depth is insufficient to compensate for their diminished frequency, so that upon the whole less air traverses the lungs. In compressed air the maximum respiratory capacity is notably augmented. The diaphragm and the base of the lung occupy a position below their usual level. Respiration is therefore performed with a permanently expanded condition of the thorax. This is no doubt one of the causes of the benefit experienced by asthmatics, and the effect continues for some time after return to air of ordinary pressure. The proportion of gases contained in the blood is only to a slight extent dependent on the pressure.* The experiments of M. P. Bert† have shown that when animals are made to respire pure oxygen gas under a pressure of five or six atmospheres (or, which is the same thing, when the pressure of the ordinary air is raised to 20 atmospheres) it acts like a poison—convulsions resembling those produced by strychnia occurring. These set in, in dogs, when the blood contains about 10 per cent. more oxygen than normal, and it is remarkable that the convulsions continue after the animal has been withdrawn from the pressure and its blood only contains the usual proportion of oxygen. With augmented barometric pressure the amount of Oxygen contained in the arterial blood of a living animal augments but with extreme slowness. The amount of Nitrogen increases more rapidly, but still far below what is required by Dalton's law, and the amount of Carbonic acid almost always diminishes. The effects of diminution of pressure in some respects resemble those of exalted pressure. Thus, Hoppe‡ observed that when rats were placed under the receiver of an air-pump and exhaustion made till the pressure was reduced to 2 inches of mercury, fainting and convulsion were usually induced, and when it was reduced to $1\frac{3}{4}$ in. (40 mm.) death occurred, apparently from the evolution of gas in the capillaries of the lungs, which impeded the passage of the blood. The singular effects observed by Glaisher§ in his lofty balloon ascents at an altitude of 7 miles—viz., loss of power in the arms and legs, failure of vision, and syncope, were probably due to the sudden and combined influence of cold, and an insufficient supply of oxygen. Less marked phenomena characterise the condition known to Alpine climbers as the Mal de montagne. They appear, however, at much lower levels than in aëronautic expeditions, on account, probably, of the muscular fatigue and want of sleep undergone. The symptoms of the affection—breathlessness, nausea or vomiting, palpitation, exhaustion, feeling of coldness, humming in the ears, and congestions of various parts, are usually experienced at a height of about 12–14,000 feet, and ascents of these altitudes should not be undertaken by those who suffer from disease of the heart, or who have a predisposition to apoplexy. The symptoms of the Mal de montagne are attributed by M. Lortet to the great consumption of heat that takes place in order to develop the amount of muscular force required. Nevertheless, both man and animals are capable of accommodating themselves to the diminished atmospheric pressure of great heights, the town of Potosi being 13,265 feet above the level of the sea, Ancomarco 15,258 feet, and Deba 15,920 feet.

289. The aëration of the blood may take place, not only by means of the Lungs, but also in some degree through the medium of the Cutaneous surface, which presents an extent of 1500 square centim. In some of the lower tribes

of animals, indeed, this is a very important part of the respiratory process; and even in certain Vertebrata the cutaneous respiration is capable of supporting life for a considerable time. This is especially the case in the Batrachia, whose skin is soft, thin, and moist; and the effect is here the greater, since, from the small proportion of the blood that has passed through the lungs, that which circulates through the system is very imperfectly arterialized. By the experiments of Bischoff it was ascertained that, even after the lungs of a Frog had been removed, a quarter of a cubic inch of Carbonic acid was exhaled from the skin in the course of eight hours. Experiments on the Human subject leave no room for doubt that a similar process is effected through the medium of his general surface, although in a very inferior degree, owing to the thickness of the epidermis, for by confining the body in a close chamber, into which the products of cutaneous respiration could freely pass, whilst the pulmonary respiration was measured by a distinct apparatus, Prof. Scharling* believed he had ascertained that the proportion of Carbonic acid given off by the Skin, the surface presented by this being estimated at 1·6 sq. metre, is from 1-40th to 1-60th of that exhaled from the Lungs during the same period of time, or from 350 to 500 grains per diem. Dr. Ed. Smith enclosed the whole of his body, except the head, in a caoutchouc bag, passed a current of air through it, and collected the Carbonic acid. The whole quantity obtained in Summer, including that found in the air of the room was 144 grains per diem, or somewhat more than 1 per cent. of the amount passing off by the Lungs. Reinhard,† estimated it at from 34 to 35 grains per diem (2·23 grammes); Röhrig‡ at 216 grains; Fubini and Ronchi§ at 105 grains; and Aubert,‖ at about 60 grains per diem, a quantity that is not equivalent to $\frac{1}{2}$ per cent. of the amount eliminated by the lungs (13-14,000 grains). Moreover, it has been observed, not unfrequently, that the livid tint of the skin which supervenes in Asphyxia, owing to the non-arterialization of the blood in the lungs, has given place after death to the fresh hue of health, owing to the reddening of the blood in the cutaneous capillaries by the action of the atmosphere upon them; and it does not seem improbable that, in cases of obstruction to the due action of the lungs, the exhalation of Carbonic acid through the skin may undergo a considerable increase; for we find a similar disposition to vicarious action in other parts of the excreting apparatus. There is also evidence that the interchange of gases between the air and the blood, through the skin, has an important share in keeping-up the temperature of the body (CHAP. XII.); and we find the temperature of the surface much elevated in many cases of pneumonia, phthisis, &c., in which the lungs seem to perform their function very insufficiently.

290. The total amount of Carbonic acid daily given-off from the Skin and Lungs may be estimated in another mode—namely, by determining the total amount of Carbon contained in the *ingesta*, and the amount excreted in other ways, making allowance for the difference in weight (if any) of the body. In this mode, Prof. Liebig came to the conclusion that the average amount of carbon exhaled by soldiers in barracks was 13·9 ozs. (Hessian) or very nearly 14 ozs. troy. From similar collective observations upon the inmates of the Bridewell at Marienschloss (a prison where labour is enforced), he calculated that each individual exhaled 10·5 ozs. of Carbon daily in the form of Carbonic acid; while in a prison at Giessen, whose inmates are deprived of all exercise,

* "Ann. der Chem. und Pharm.," 1846. † "Zeitschrift für Biologie," Band v. 1869, p. 37.
‡ Pflüger's "Archiv," Band vi. 1872, p. 539. § "Deutsche Klinik," 1872, p. 209.
‖ Pflüger's "Archiv," Band vi. 1872, p. 539.

the daily average was but 8·5 ozs.* A very exact estimate, though based on more limited data, was made by M. Barral,† who experimented upon himself (æt. 29) in winter (A) and in summer (B), upon a boy 6 years old (C), upon a man 59 years old (D), and upon an unmarried woman of 32 years (E). The following Table gives the results which he obtained, from an average of five days, in regard to the disposal of the Carbon of the food; those which relate to its Nitrogen, Hydrogen, and Oxygen will be noticed subsequently.

	Weight of Body.	*Carbon of Food.*	*Carbon excreted.*		
			In Fæces.	In Urine.	By Exhalation.
A	104·5 lbs.	5654·1 grs.	236·2 grs.	234·6 grs.	5183·3 grs.
B	——	4090·0 „	137·4 „	211·5 „	3741·1 „
C	33 „	2382·3 „	149·7 „	67·9 „	2164·7 „
D	129·1 „	5123·0 „	210·0 „	327·3 „	4585·7 „
E	134·6 „	4520·8 „	64·8 „	216·1 „	4239·9 „

Thus, the average amount of the Carbon daily consumed in pulmonary and cutaneous exhalation by M. Barral himself, was in winter 5183·3 grains, or 10·8 ozs. troy; whilst in summer it was but 3741·1 grains, 7·8 ozs. troy. This difference is quite conformable to what might have been anticipated from the results of a different mode of experimenting; and it throws some light on the discrepancies in the results of other measurements, to find that the seasonal variation is scarcely less than one-third of the mean between these two amounts. The other results correspond closely with the statements of MM. Andral and Gavarret, in regard to the higher proportion of Carbonic acid exhaled (as compared with the bulk of the body) by children, and the smaller proportion thrown off by men advanced in years, and by women. In some experiments made on himself in Pettenkofer's apparatus, Ranke (weighing 161 lbs.) found that, when at rest and fasting, 10,190 grains of Carbonic acid or 2779 grains of Carbon were eliminated in twenty-four hours by the Skin and Lungs, whilst with as full a diet as possible the amount was 13,278 grains of Carbonic acid or 3621 grains of Carbon. Rubini and Ronchi experimented on the fore-arm and hand confined in a chest, and found that more CO_2 gas is given off by day than by night in the proportion of 113 : 100. The quantity rises, with augmented temperature, considerably. It is during fasting (15–18 hours after the last meal) somewhat less than during digestion, the proportion being as 100 : 112. It is greater with pure vegetable than with animal food. The amount in one individual eliminated in 24 hours was 425 millegrammes. A certain interchange of gases must also take place in the intestinal canal. This, though of small amount in man, is of considerable importance in many of the lower animals, as in many fish and insects.

291. It is not only by an oxygenated atmosphere that the removal of Carbonic acid from the blood may be effected. For although it was formerly supposed that the exhaled Carbonic acid is generated in the lungs by the combination of atmospheric oxygen with the carbonaceous matters of the blood, and that the inhalation of oxygen is therefore immediately necessary for its production, yet it is now quite certain that this Carbonic acid exists preformed in venous blood, and that the oxygen introduced is carried into the arterial circulation, instead of being at once returned to the air in a state of Carbonic acid. Hence an exhalation of Carbonic acid may continue for a considerable period (in cold-blooded animals especially), whilst the animal is breathing an atmosphere in which no oxygen exists. Thus, it was shown by Spallanzani,‡ that snails might be kept for a long time in Hydrogen without

* Op. cit., p. 46. † "Ann. de Chim. et de Phys.," tom. xxv.
‡ "Mémoires sur la Respiration," traduit par Senebier, Genève, 1804.

apparent injury to them; and that during this period they disengaged a considerable amount of Carbonic acid. Dr. Edwards* subsequently ascertained that, when Frogs were kept in hydrogen for several hours, the quantity of Carbonic acid exhaled was fully as great as it would have been in atmospheric air, or even greater. This latter fact, which, however, is very doubtful, might be accounted for by the superior displacing power which (on the laws of the diffusion of gases) hydrogen possesses for Carbonic acid. Collard de Martigny† repeated this experiment in Nitrogen, with the same results. In both sets of experiments, the precaution was used of compressing the flanks of the animal, previously to immersing it in the gas, so as to expel from the lungs whatever mixture of oxygen they might contain. These experiments have since been repeated by Müller and Bergmann, who took the additional precaution of removing, by means of the air-pump, all the atmospheric air that the lungs of the frog might previously contain, together with the Carbonic acid that might exist in the alimentary canal. They found, in one of their experiments, that the quantity of Carbonic acid exhaled in hydrogen was nearly a cubic inch in $6\frac{1}{2}$ hours; and in another, that nearly the same amount was given-off in nitrogen, though this required rather a longer period. It appears from the table of their results,‡ that the amount was not ordinarily greater in the experiments which were prolonged for twelve or fourteen hours than in those which were terminated in half the time; hence it may be inferred that the quantity which the blood is itself capable of disengaging is limited, and that the antecedent absorption of oxygen and its storage in the tissues§ is necessary to enable Carbonic acid to be continuously set-free from the body.—It is impossible, however, for an *adult* Bird or Mammal to sustain life for any considerable time in an atmosphere deprived of oxygen; since the greatly-increased rapidity and energy of all their vital operations necessitate a much more constant supply of this vivifying agent than is needed by the inferior tribes; and, as we shall presently see, the capillary action requisite for the passage of the blood through the lungs will not take place without it. But Dr. Edwards has shown that *young* Mammalia can sustain life in an atmosphere of hydrogen or nitrogen for a sufficient length of time to exhale a sensible amount of Carbonic acid; so that the character of the process is clearly proved to be the same in warm-blooded animals as in Reptiles and Invertebrata.

292. The seat of those changes which result in the formation of Carbonic acid has been the subject of much research and discussion. It may either be conceived that the oxygen taken up by the blood corpuscles, and feebly held in combination by their hæmoglobin, escapes by diffusion through the blood-vessels, and directly enters into combination with the constituents of the tissues, the Carbonic acid formed being given up in exchange for fresh oxygen, which is at once stored up in the tissues; or we may suppose that the products of the disintegration of the tissues enter the blood, and there meeting with the loosely combined oxygen, abstract it from the corpuscles, which readily surrender it to the more oxidizable materials. In the one case, the oxidizing process and the production of Carbonic acid would take place chiefly in the tissues, in the other chiefly in the blood. Various circumstances seem to point to the former as being the more correct statement of the facts.‖ In the first place, the respiration of the tissues shown to occur by Liebig and P. Bert

leads to the development of Carbonic acid within them, and as they contain (at least in the case of the most important of all—the muscles) no oxygen capable of being removed by exhaustion, the oxygen contained in arterial blood will in obedience to physical laws diffuse into the tissues, and be replaced by Carbonic acid. Again, it may be shown that arterial blood loses its oxygen with extraordinary rapidity during its passage through the capillaries, and although this was attributed by Schmidt to the presence of easily oxidizable or reducing substances in the blood, chiefly associated with the corpuscles (Afanassieff), yet Pflüger* has shown that the quantity of these oxidizable substances can be but small, since arterial blood removed from the body only slowly acquires a venous character, whilst even in the case of asphyxiated animals, warmth and time are required for the production of a large amount of Carbonic acid; and so too, if an easily oxidizable substance, as sodium lactate, glycerin, grape sugar, or caproic acid, be added to blood after withdrawal from the body, no augmentation in the amount of Carbonic acid is observed, though if injected into the circulation such substances are quickly decomposed, and cause increased evolution of this gas.† The fact noticed by Ludwig and Hammarsten, that the tension of the Carbonic acid in the lymph is lower than in venous blood, though higher than in arterial, constitutes no valid objection to the view that the gas is chiefly formed in the tissues and not in the blood, since the lymph examined by them had already had the opportunity of equalizing the tension of its gases with those of arterial blood in traversing the lymphatic glands and the lacunæ of the connective tissues. At the same time, the phenomena of oxidation are materially affected by the integrity of the blood corpuscles, since these are the carriers of the oxygen, or perhaps, more properly speaking, of ozone; for, as Ritter‡ has shown in his investigations on the influence of agents which modify the absorptive capacity of the corpuscles for oxygen, the secretions undergo material alterations when the corpuscles have been profoundly altered by the action of antimonial and arsenical compounds, by phosphorus, or by the action of the biliary acids; these agents changing the form of the corpuscles, and causing the appearance of crystals of Hæmoglobin in the blood, coinciding with which the urine becomes albuminous, and contains various colouring materials. In connection with this, the observations of Manassein§ may be mentioned, as showing that the red corpuscles diminish in volume when under the influence of abnormal activity of the disintegrating processes, as in Febrile states when they have to part with an increased amount of oxygen; or when any obstacle exists to the absorption of oxygen, as when they are exposed to the action of carbonic acid or morphia; whilst they augment in size when they are exposed to a highly oxidized medium, or when they are placed under conditions in which the oxygen escapes with difficulty, as after the administration of refrigerants, quinine, alcohol, and hydrocyanic acid. Whether the carbonic acid is chiefly formed without or within the vessels, it is certain that the amount developed

* Pflüger, 'Ueber die Diffusion des Sauerstoffs, &c.,' Pflüger's "Archiv," Band vi. 1872, p. 43.

† Ludwig and Schremetjewsky (Ludwig's "Arbeiten," 1868) have, however, shown that sugar passes through the capillaries of the kidneys unchanged. It has been shown by Oertemann (Pflüger's "Archiv," Band xv. 1877, p. 381) that if a frog be thoroughly deprived of blood, and the vessels refilled with ·75 per cent. solution of common salt, life may be preserved from two to three days.

§ "Ueber die Dimensionen der rothen Blutkörperchen unter verschiedenen Einflüssen." Pamphlet, 1872.

bears a close relation in all parts of the body with the energy with which cell growth and function take place, and with the activity of the interstitial changes coincident with these processes; the blood, which has then become charged with this gas and poor in oxygen, is conducted to the lungs, when the converse changes are effected, the Carbonic acid diffusing through the vessel into the air contained in the pulmonary alveoli, and being replaced by oxygen. On the whole, the absorption of oxygen from the air into the venous blood is to be regarded as an exclusively chemical process, and as dependent upon the affinity of reduced Hæmoglobin for Oxygen, for the quantity of oxygen absorbed is the same whether the animal breathe pure oxygen or a mixture of oxygen and nitrogen, and an animal placed in a confined space continues to breathe till nearly all the oxygen is used up. The tension of the oxygen in the blood is very low, amounting in arterial blood to 29·6 mm. of mercury, which corresponds to an amount of 3·9 per cent., and in venous blood to 22 mm., corresponding to 2·9 per cent.,* whilst the tension of the O of the atmospheric air amounts to 158 mm. of mercury, corresponding to the presence of 20·8 vol. per cent. The elimination of Carbonic acid, on the other hand, from the blood is partly due to its expulsion by the oxygen which takes its place, and partly to the high tension at which it exists, and the natural tendency to diffusion. The tension of the Carbonic acid gas in arterial blood is equal to 21 mm. of mercury, corresponding to 2·8 vol. per cent., and in venous blood to 41 mm., corresponding to 5·4 vol. per cent., whilst the tension of this gas in the air is only 0·38 mm., corresponding to 0·03–0·05 per cent; there is consequently a strong tendency for the Carbonic acid to escape from the blood and to diffuse into the air contained in the alveoli of the lungs. This is regarded as the effect of the formation of oxyhæmoglobin, the expulsion of the Carbonic acid being dependent on the absorption of oxygen.

293. Much discussion has taken place with regard to the degree in which the proportion of *Nitrogen* in the air is affected by Respiration. It seems probable that the absorption and exhalation of this gas are continually taking place; but that the two amounts usually nearly balance each other.† On the whole, however, there is adequate reason to believe that Nitrogen is ordinarily given-off; this being the joint result of the analysis of the expired air, and of the comparison of the amount of nitrogen given-off in the other excretions with that ingested as a constituent of the food. In some experiments made by Regnault and Reiset, on the composition of the expired air in various warm-blooded animals, they arrived at the following conclusions:—(1). That warm-blooded animals subjected to their ordinary regimen exhale nitrogen, but never in larger proportion than 1–50th, and sometimes in less than 1–100th, of the oxygen consumed;—(2). That in a state of inanition, animals usually absorb nitrogen;—(3). That animals whose usual diet has been changed, usually absorb nitrogen until they are accustomed to their new food.‡—Voit,§ in experiments on pigeons extending over 124 days, found that little or no nitrogen is eliminated by the lungs in these animals, since the amount contained in the urine and fæces was equal to within 2·3 per cent. of that ingested. This result is in marked contrast to that obtained by Boussingault, who found a deficit of 35 per cent. of nitrogen in the fæces and urine, when compared with that contained in the food. From Seegen's researches

* Worm Müller, Ludwig's "Arbeiten," 1871, p. 119.

§ Henle and Meissner's "Bericht," 1862, p. 342, and 1866, p. 390.

on dogs,* it appears that although generally the greater part of the nitrogen is eliminated as urea, under certain circumstances a large portion (one half) may be discharged by other channels, a portion probably escaping by the lungs; and more recently Seegen, in conjunction with Nowak† have satisfied themselves that nitrogen is eliminated in the proportion of 5·7 to 6·0 ingested in the gaseous form or about 10 per cent. of the total excretions of nitrogen. Barral estimated that the amount of nitrogen which (being otherwise unaccounted for) must be considered to have passed off by the lungs and skin in Man, varied from 1-75th (in an adult) to 1-143rd (in a child) of the nitrogen consumed, the former proportion agreeing very well with that deduced by MM. Regnault and Reiset from their experiments on animals.

[The alterations effected in the *Blood* by Respiration have already been fully considered. See §§ 196-197.]

294. *Exhalation and Absorption through the Lungs.*—The Air expired from the lungs differs from that which was introduced into them, not merely in the altered proportions of its Oxygen, Nitrogen, and Carbonic acid, but also in having received (under ordinary circumstances, at least) a large addition to its watery vapour. This it doubtless acquires in accordance with physical laws, through its exposure to the warm blood which is spread-out over a very extensive surface, the intermediate membrane being extremely permeable; and the variations in its amount will depend upon the physical conditions under which that exposure takes place. The air expired in ordinary respiration is charged with as much watery vapour as saturates it at the temperature of the body;‡ and consequently the amount of watery vapour thus exhaled will vary (for equal volumes of air at any given temperature) in the inverse proportion to that which the air previously contained. But when the air is very cold and very dry, and the respiration is unusually rapid, or when the amount of fluid in the body is greatly diminished, as after long fasting, it may not remain sufficiently long in the air-cells to be raised to the temperature of the body, or to be fully saturated with moisture. The amount of watery vapour exhaled, moreover, will of course depend in part upon the quantity of air which passes through the lungs. And from these causes of difference it happens that the amount of watery vapour exhaled in twenty-four hours may vary from about 6 ozs. to 27 ozs.; its usual range, however, being between 7 and 11 ozs.§ Weyrich‖ estimates the amount of insensible perspiration by the skin and lungs for a man weighing 125 lbs. at 14,500 grains, or 2 lbs. avoirdupois per diem, and the proportion of water discharged by the skin to that by the lungs as 2 : 3. Dr. Ed. Smith found that during a long fast the quantity of vapour exhaled by the lungs was 2·02 grs. per minute, or ·548 gr. in every 100 cub. in. of expired air. With food and at rest, the quantity varied from 3 grs. to 3·4 grs. per minute. The inhalation of alcoholic vapours increased the quantity of vapour exhaled; when alcohol was drunk the quantity was also increased, but it was decreased under the action of gin.—Of the fluid ordinarily exhaled with the breath, a part doubtless proceeds from the moist lining of the nostrils, fauces, &c.; but it is indisputable that the greater proportion of it comes from the lungs, since, when the respiration is entirely performed through a canula introduced into the trachea, the amount of watery vapour which the breath

* "Wiener Sitzungsberichte," 1867, March, Band lv.

† Pflüger's "Archiv," vol. xix. 1879, p. 347.

‡ The tension of the watery vapour of expired air amounts, according to Weyrich, when reduced, to 0° C. and 760 mm. pressure to 4·36 mm. of mercury, which is nearly that of air saturated with aqueous vapour (4·5 mm.).

§ Valentin's estimate is 8333 grains in the 24 hours from the lungs alone. Vierordt's 5092 grains.

‖ "Observations," &c., Dorpat, 1865, 8vo.

contains is still very considerable. Of the proper pulmonary exhalation, there can be no doubt that the greater part is the mere surplus-water of the blood, and especially of the crude fluid which has been newly introduced into the circulating current by the process of nutritive absorption. But there is strong evidence that Hydrogen as well as Carbon undergoes combustion in the system, and that a portion of the exhaled aqueous vapour is the product of that combustion. For of the hydrogen which the food contains, not more than from 1-8th to 1-10th passes off by the other excretions, the remaining 7-8ths or 9-10ths being exhaled in the condition of watery vapour from the lungs. A portion of the oxygen which this vapour contains is supplied by the food; but there is usually a considerable surplus of hydrogen, and this can only be converted into water at the expense of oxygen derived from the atmosphere.

295. The fluid thrown-off from the lungs is not pure water. It holds in solution, as might have been expected, a considerable amount of Carbonic acid, and also some animal matter, which, from the inquiries of Dr. R. A. Smith,* would appear to be an albuminous substance in a state of decomposition. A small quantity of Ammonia is usually, but perhaps not always, thrown-off.† It has been suggested that this, when present, may be derived either from decomposing fragments of food or from carious teeth; but Thiry believed he had demonstrated it in air expired to avoid contamination through a canula introduced into the trachea of a rabbit. The test used was Nessler's (solution of iodide of mercury and iodide of potassium). Ransome estimates that an amount of Ammonia representing about 3 grains of organic matter are eliminated by an adult man in twenty-four hours. Lossen, however, estimates it at only 0·014 grain per twenty-four hours.‡ According to Wiederhold,§ the Chlorides of Sodium and Ammonium, Uric Acid and the Urates of Soda and Ammonia, may be detected in the expired air. Ransome found a small quantity of Urea in one or two instances. If the fluid be kept in a closed vessel, and be exposed to an elevated temperature, a very evident putrid odour is exhaled by it. Every one knows that the breath itself has, occasionally in some persons, and constantly in others, a fœtid taint; when this does not proceed from carious teeth, ulcerations in the air-passages, disease in the lungs, or other similar causes, it must result from the excretion of the odorous matter, in combination with watery vapour, from the pulmonary surface. That this is the true account of it seems evident from the analogous phenomenon of the excretion of turpentine, camphor, alcohol, and other odorous substances which have been introduced into the venous system, either by natural absorption, or by direct injection; and also from the suddenness with which it often manifests itself, when the digestive apparatus is slightly disordered, apparently in consequence of the entrance of some mal-assimilated matter into the blood. Among the substances occasionally thrown-off by the lungs, Phosphorus deserves a special mention, on account of the peculiarity of the form under which it is eliminated; for it has been found that if phosphorus be mixed with oil, and be injected into the

§ "Deutsche Klinik," 1858. Schenk states that a small quantity of ammonia is eliminated by the lungs in the Rabbit, Guinea Pig, and Dog, but none by the skin. The nature of the food has no influence on the quantity (Pflüger's "Archiv," Band iii. p. 470.

blood-vessels, it partly escapes in an unoxidized state from the lungs, rendering the breath luminous.* And this luminous breath has also been observed in spirit-drinkers, in whom the oxidation of the effete matters of the system is impeded, in consequence of the demand set-up by the alcohol ingested for the oxygen introduced (§ 290, vi). The poisonous effects of air which has been already breathed are much more marked than air charged with the same amount of Carbonic acid gas, evidently in consequence of the organic impurities with which it is charged.

296. Not only exhalation, but also (under peculiar circumstances) *absorption* of fluid may take place through the Lungs. Thus Dr. Madden† has shown that, if the vapour of hot water be inhaled for some time together, the total loss by exhalation is so much less than usual, as to indicate that the cutaneous transpiration is partly counterbalanced by pulmonary absorption; the pulmonary exhalation being at the same time entirely checked. It is probable that, if the quantity of fluid in the blood had been previously diminished by excessive sweating, or by other copious fluid secretions, the pulmonary absorption would have been much greater. Still, in the cases formerly mentioned (§ 147), in which a large increase in weight could only be accounted-for on the supposition of absorption of water from the atmosphere, it seems probable that the cutaneous surface was chiefly concerned; for it can only be when the air introduced into the lungs is *saturated* with watery vapour that the usual exhalation will be checked, or that any absorption can take place.

297. That absorption of other volatile matters diffused through the air, however, is continually taking place by the Lungs, is easily demonstrated. A familiar example is the effect of the inhalation of the vapour of Turpentine upon the urinary excretion. It can only be in this manner that those gases act upon the system, which have a noxious or poisonous effect when mingled in small quantities in the atmosphere; and it is most astonishing to witness the extraordinary increase in potency which many substances exhibit, when they are brought into relation with the blood in the gaseous form. The most remarkable example of this kind is afforded by Arseniuretted Hydrogen, the inspiration of a few hundredths of a grain of which has been productive of fatal consequences, the resulting symptoms being those of arsenical poisoning. Next to this, perhaps, in deleterious activity, is Sulphuretted Hydrogen; but it would seem that the effects of this gas upon the Human subject are scarcely so violent as they are upon animals; for though it has been found that the presence of 1-500th part of it in the respired air will destroy a bird in a very short time, that 1-800th part suffices to kill a dog, and that 1-250th part is fatal to a horse, yet M. Parent-Duchâtelet has affirmed that workmen habitually breathe with impunity an atmosphere containing *one per cent.*, and that he himself has respired, without serious symptoms ensuing, air which contained *three per cent.* There can be no doubt, however, that the *continued* inhalation of air thus contaminated would be speedily fatal. Sulphuretted hydrogen and Ammonium Sulphide are given off from most forms of decaying animal and vegetable matter; and it is undoubtedly to the accumulation of these gases that the fatal results which sometimes ensue from entering sewers are to be chiefly attributed.—Antimoniuretted and Phosphuretted hydrogen may also be included with the above as poisonous gases. These all oxidize themselves at the expense of the oxygen of the blood,‡ and as a result of this

appropriation, induce dyspnœa, convulsions, and asphyxia. Other poisonous gases, as Carbonic oxide* (practically destroying the red blood-corpuscles), Deutoxide of Nitrogen, and Cyanuretted Hydrogen, according to Hermann,† form a group that displace the oxygen and enter into combination with the hæmoglobin, producing a clear red solution, and inducing the same symptoms as the former. Deutoxide of Nitrogen is, however, properly included under the irrespirable gases. Other poisonous gases, again, as Protoxide of Nitrogen, Olefiant gas, Chloroform, and Carbonic acid, are intoxicating in their properties, affecting the functions of the brain, and ultimately producing a narcotic effect. Amongst the irrespirable gases which, unless exceedingly diluted, induce spasm of the glottis, may be enumerated Carbonic acid, Hydrochloric acid, Binoxide and Peroxide of Nitrogen, Ammonia, Chlorine, and Ozone. If introduced through a tracheal fistula, all of them act as poisons. Finally, Nitrogen, Hydrogen, and perhaps Carburetted hydrogen, may be considered as indifferent gases, proving fatal when breathed in a state of purity, by permitting the accumulation of carbonic acid in the blood, and by failing to supply oxygen.—Cyanogen is another gas which has an actively-poisonous influence upon animals, when absorbed into the lungs. Its agency is of a narcotic character, but has not been accurately investigated.

298. The respiration of pure Oxygen for short periods, 7—17 minutes in Man,‡ produces no effect either on the rapidity of the pulse or upon the temperature of the body, and scarcely any more of this gas is absorbed than under ordinary circumstances, which, as Pflüger, has shown, is owing to the fact that arterial blood is charged normally with nine-tenths of the whole amount of oxygen it can take up. In small chambers§ the whole of the oxygen is used up, but if the chamber be large, the amount of carbonic acid produced proves fatal before the complete consumption of the oxygen. If an animal be placed in an atmosphere of pure oxygen with no provision for the removal of the carbonic acid eliminated, death takes place when the proportion of this gas amounts to 20—30 per cent., though the quantity of Oxygen may still amount to from 70—80 per cent. When all the Carbonic acid eliminated is removed, as fast as formed, death occurs in mammals when the amount of Oxygen falls to 2 per cent., and in birds when it is reduced to between 3 and 4 per cent.‖ Animals made to breathe Oxygen at a pressure of 5 or 6 atmospheres, or which are exposed to ordinary air at a pressure of 20 atmospheres, fall into violent convulsions, which last even after the pressure has been reduced to the normal. It would therefore appear that the Oxygen in entering the blood at this high pressure forms one or more compounds with some of its constituents, acting like strychnia. The most interesting recent researches in regard to the effects of respiring air more or less contaminated with Carbonic acid gas, and with varying amounts of Oxygen, are those of Friedländer and Herter,¶ which, whilst generally corroborating the results obtained by M. Bert, show that a marked distinction must be drawn between

the effects produced by large and small quantities of Carbonic acid gas; small doses including all quantities up to 20 per cent.; large doses, quantities varying from 20 to 65 per cent. The addition of Carbonic acid gas was made solely at the expense of the Nitrogen of the air, and the amount of Oxygen in the gas mixture supplied to the animal was maintained at the normal standard of 21 per cent. With small doses, corresponding to 11—13 per cent. of Carbonic acid gas, the animals exhibited some dyspnœa, the respirations being deeper and more frequent, the action of the heart was increased, but the temperature remained unchanged, and no poisonous effects were observed, even in the course of an hour. The dyspnœa rapidly vanished when the animals (rabbits) were removed from the bell-glass under which they had been confined. When the quantity of Carbonic acid gas in the air supplied was increased to about 30 per cent. the phenomena of stimulation, above noted, lasted only for a short time, and were succeeded by depression; the respirations became feebler and shallower, the blood-pressure sank gradually, and voluntary and reflex activity gradually failed. The temperature also fell considerably, and the animal after the lapse of some hours died. With maximum doses the period of excitation became reduced in duration to a few minutes, the cardiac excitation, as indicated by the increased blood-pressure, lasting longer than the respiratory excitation, whilst the phenomena of depression soon set in, and death occurred in the course of half an hour, being preceded by arrest of the respiration and of the heart's action. In regard to the effects of a deficiency of Oxygen, it appears* that animals breathe tranquilly when the proportion of Oxygen is only 14·8 per cent.; with 7 per cent. they begin to be dyspnœic. With 4·5 per cent. the dyspnœa is severe, and with 3 per cent. there is rapid asphyxia. If the withdrawal of the supply of Oxygen be sudden, the animal being placed in an indifferent gas, dyspnœa, rapidly increasing in intensity, supervenes, with clonic spasms of the muscles of the body generally. There is then a long respiratory pause, which is followed by exophthalmus and dilatation of the pupils. Finally, a few weak respiratory movements are made before death, which usually takes place in rabbits in the course of from $1\frac{1}{2}$ to 2 minutes. Now, in the case of Carbonic acid poisoning, even when the proportion of CO_2 is 80 per cent. to 20 per cent. of Oxygen, the duration of life is at least ten times longer, and the dyspnœa is less immediate in its appearance. Loss of consciousness and of the reflex movements is observed in the course of the first minute in CO_2 poisoning, but when these phenomena occur in acute withdrawal of Oxygen it is the immediate presage of death. Moreover, CO_2 narcosis may last for half an hour without danger to life, whilst loss of consciousness from withdrawal of Oxygen can only last a very short time if life is to be preserved by admitting a fresh supply. If an animal be placed in a confined space, with a supply of ordinary air, and the CO_2 be absorbed as fast as it is formed, so as to avoid any ill effects from its accumulation, it is found that the quantity of Oxygen is reduced when death occurs from 3·8 to 2·1 per cent.† Here also dyspnœa (deeper and more frequent respiratory acts) occurred, which gradually increased to orthopnœa, the head being thrown back and the nostrils powerfully dilated. One of the most marked differences between the toxic influence of an excess of CO_2 and the withdrawal of O occurs during the last few minutes of life, which in the former is accompanied by a gradual cessation of the respiratory movements, whilst in the latter there are phenomena of violent excitation of the nervous and muscular systems which last for a few moments, and the

* W. Müller, Friedländer, and Herter, "Zeits. f. physiol. Chemie," Band iii. 1879, p. 21.

† Friedländer and Herter, loc. cit., p. 24. Bernard found it vary from 3 5 per cent.; Stroganow, Pflüger's "Archiv," Band xii. 1875, p. 30, from 3 to 4 per cent.

respiration then suddenly ceases and the animal falls dead. Post-mortem examination showed that the lungs were somewhat hyperæmic, but they rarely exhibited ecchymoses or any œdema, which is so common in CO_2 poisoning. In regard to the blood-pressure there was no primary fall as in CO_2 poisoning, but an increase which lasted till just before death, when it suddenly fell.* The pulse always fell in frequency when the quantity of Oxygen was below 4 per cent. It cannot be doubted that Miasmata and other morbific agents diffused through the atmosphere are more readily introduced into the system through the pulmonary surface than by any other; and our aim should therefore be directed to the discovery of some counteracting agents which can be introduced in the same manner. The pulmonary surface affords a most advantageous channel for the introduction of certain medicines that can be raised in vapour, when it is desired to affect the system with them speedily and powerfully; such is pre-eminently the case with the various anæsthetic agents, such as ether and chloroform, whose introduction into the various departments of Medical and Surgical practice constitutes a most important era in the history of the healing art; also with Mercury,† Iodine, Tobacco, Stramonium, &c., and it has recently been shown by M. Jousset that direct injection through the trachea is a means by which quinine may be made to enter the system rapidly, when the state of the cutaneous circulation and the irritability of the stomach render it useless to administer it either by the stomach or by subcutaneous injection.‡

3. *Effects of Suspension or Deficiency of Respiration.*

299. We have now to consider the results of the cessation of the Respiratory function, and the consequent deficiency in the supply of Oxygen and retention of Carbonic acid in the blood. If this be sufficiently prolonged, a condition ensues to which the name of *Asphyxia* has been given, the essential character of which is the cessation of muscular movement, and shortly afterwards of the Circulation; with an accumulation of blood in the venous system. The time which is necessary for life to be destroyed by Asphyxia varies much, not only in different animals, but in different states of the same. Thus, warm-blooded animals are much sooner asphyxiated than Reptiles or Invertebrata; on the other hand, a hybernating Mammal supports life for many months, with a respiration sufficiently low to produce speedy asphyxia if it were in a state of activity. And among Mammalia and Birds there are many species which are adapted, by peculiarities of conformation, to sustain a deprivation of air for much more than the average period.§ Excluding these, it may be stated as a general fact, that if a warm-blooded animal in a state of activity be deprived of respiratory power, its muscular movements (with the exception of the contraction of the heart) will cease within five minutes, often within three; and that the

* An increase of pressure was also observed by Thiry, "Zeits. f. rat. Med.," Band xxxi. p. 17; as well as G. Heidenhain, Grützner, and others, but it was not constant in the experiments of Goldstein (Pflüger's "Archiv," Band xvii. p. 343); nor by Zuntz (idem, Band xvii. p. 374).

† The beneficial results of the introduction of Mercury by inhalation are strikingly set forth in Mr. Langston Parker's Essay on "The Treatment of Secondary, Constitutional, and Confirmed Syphilis." ‡ Claude Bernard, "Leçons sur les Anæsthésiques," 1875, p. 74.

§ Thus, the Cetacea contain far more blood in their vessels than do any other Mammalia; and these vessels are so arranged, that both arteries and veins are in connection with large reservoirs or diverticula. The reservoirs belonging to the former are usually full; but when the Whale remains long under water, the blood which they contain is gradually introduced into the circulation, and after becoming venous, accumulates in the reservoirs connected with the venous system. By means of this provision, the Whale can remain under water for more than an hour.

circulation generally fails within ten minutes. In the experiments made by the Committee of the Royal Medico-Chirurgical Society,* which are corroborated by the more recent ones of M. P. Bert,† it was found that when death by drowning took place rapidly, it was due to the entrance of Water into the lungs; and that if the entrance of air into the lungs was prevented by suddenly inserting a cork into a glass tube tightly tied into the trachea, the average duration of the efforts to inspire was 4 minutes 5 seconds in dogs, and 3 minutes 25 seconds in rabbits; whilst the average duration of the heart's action was 7 minutes 11 seconds in dogs, and 7 minutes 10 seconds in rabbits. It was found also that in simple occlusion of the trachea recovery might take place after deprivation of air for 3 minutes 50 seconds, whilst immersion for 1½ min. was usually fatal.—M. Brown-Séquard‡ has shown by numerous experiments, that both newly-born animals and adults are capable of resisting the Asphyxia which results from submersion by so much longer a period as their temperature is lower, providing it does not descend below 64° F. As a general rule, the newly-born animal can survive submersion for a longer period than the adult; this, however, does not hold in the case of guinea-pigs. Of 14 newly-born rabbits submerged in water at 77° F., 5 had a temperature of 96½° F., and survived on the average 12½ minutes; 4 had a temperature of 82° to 89° F., and survived 17 minutes; lastly, 5 had a temperature of from 64° to 70° F., and these survived, on an average, 26½ minutes. A newly-born dog will survive, if its temperature be low, an immersion of 50 minutes' duration. A duck is capable of resisting the privation of air for seven or eight minutes, while a chicken will die from submersion or strangling in two or three. A satisfactory explanation of these peculiarities has been given by M. P. Bert, who has shown that they are dependent upon the amount of Oxygen in the blood, and the activity of the combustive processes in the tissues. As the blood-corpuscles constitute a magazine of Oxygen, the larger their number the longer will the animal be able to resist the privation of air; and so also life will be prolonged when from any cause the processes of oxidation in the tissues are lowered. M. Bert has elsewhere shown that the respiration of the tissues takes place less actively in young than in old animals, whilst it is obvious that a low temperature is less favourable for oxidation than a high one, and direct experiment has demonstrated that a duck contains one-third or even one-half more blood than a chicken. Many persons are capable of sustaining a deprivation of air for two, three, or even four minutes,§ without insensibility or any other injury; but this power, which seems possessed to the greatest degree by the divers of Ceylon, can only be acquired by habit. The period during which remedial means may be successful in restoring the activity of the vital and animal functions is not, however, restricted to this. There is one well-authenticated case in which recovery took place after a continuous submersion of fifteen minutes;‖ and many others

* "Trans.," vol. xlv. p. 449. † "Gaz. Médicale," 1865, p. 79.

‡ "Journal de la Phys.," vol. ii. p. 98, *et seq.*

§ Dr. Hutchinson states that any man of ordinary 'vital capacity' can pass two minutes without breathing, if he first makes five or six forcible inspirations and expirations, so as to cleanse the lungs of the old air, and then fills his chest as completely as he can. "For the first 15 seconds a giddiness will be experienced; but when this leaves us, we do not feel the slightest inconvenience from want of air." (See "Cyclop. of Anat. and Phys.," vol. iv. p. 1066.)

‖ The following are the facts of this case, as narrated by Marc ("Manuel d'Autopsie Cadavérique Médico-Légale," p. 165) on the authority of Prater:—A woman convicted of infanticide was condemned to die by drowning. This punishment was formerly inflicted in Germany according to the now obsolete Caroline law, the culprit being enclosed in a sack with a cock and a cat, and sunk to the bottom of the water. In this instance, the woman, after having been submerged for a quarter of an hour, was drawn up, and *spontaneously*

are on record, of the revival of drowned persons after an interval of half an hour, or even more; but there is not the same certainty in regard to these, that the individuals may not have occasionally risen to the surface and taken breath there. It is not improbable, however, that in some of these cases a state of Syncope came on at the moment of immersion, through the influence of fear or other mental emotion, concussion of the brain, &c.; so that when the circulation was thus enfeebled, the deprivation of air did not have the same injurious effect as when this function was in full activity. The case would then closely resemble that of a hybernating animal; for in both instances the being might be said to live very slowly, and would therefore not require the usual amount of respiration. The condition of the still-born infant is in some respects the same; its tissues, as just stated, are the seat of much less active processes of combustion than those of the adult, and re-animation has been successfully attempted when nearly half an hour had intervened between birth and the employment of resuscitating means, and when probably a much longer time had elapsed from the period of the suspension of the circulation.

300. The phenomena presented in Asphyxia,* whether produced by suddenly cutting off the supply of air, or more slowly by permitting the animal to breathe through a narrow chink, are very similar, though, in the latter case, the successive stages can be more easily followed. In the first instance there are violent inspiratory, followed after a short time by equally violent expiratory, efforts, which culminate in convulsions, the abdominal and other expiratory muscles being those chiefly affected. When the access of air to the lungs has been suddenly prevented, the expiratory convulsions, with spasms of the muscles of the limbs, occur within the first minute, and are so marked and peculiar as to have been attributed to the excitation of an expiratory convulsive centre. During this period the tension of the blood in the vessels is greatly increased. After the convulsions have lasted a few seconds they often cease suddenly, and are followed by a period of calm. The expiratory movements, in consequence of exhaustion, cease; efforts to inspire occur with long but tolerably regular intervals between them, and at each effort, when the occlusion of the trachea has been sudden, the blood-pressure falls, so that at the end of the second minute it is considerably less than natural; when, however, Asphyxia has been slowly produced, the blood-pressure as well as the frequency of the heart's beats continue to increase during this period. Reflex movements now cease, and the pupil becomes widely dilated and insensible to light. In suddenly produced and complete Asphyxia death ensues in the course of three or four minutes, preceded by inspiratory movements which are slow, feeble, and irregular, two or three efforts being made successively, followed by a long pause. In the spasms which accompany the final gasps the head is thrown back, the trunk is straightened or arched backward, and the limbs are extended, whilst the mouth gapes, and the nostrils dilate. These so-called stretching convulsions are of quite a different type from the previously mentioned expiratory convulsions. In regard to the variations of

recovered her senses. She stated that she had become insensible at the moment of her submersion; a circumstance which adds considerable weight to the supposition, based upon the post-mortem appearances in many cases of drowning, that death often takes place as much by Syncope (or primary failure of the heart's action, consequent upon sudden and violent emotion, or upon physical shock) as by Asphyxia. If the reality of this state of Syncopal Asphyxia be admitted, there does not seem any adequate reason for limiting the possible persistence of vitality in a submerged body, even to half an hour; especially if the temperature of the water be such as not to cause any rapid abstraction of its heat.

* See Burdon-Sanderson in the "Handbook for the Physiological Laboratory," 1873, p. 319, *et seq.*

the blood-pressure in Asphyxia, there appears to be a primary slight fall, followed by augmentation of the blood-pressure (in rabbits from 110 mm. to 140 mm.), which is not attributable to struggling or to the muscular movements attending the dyspnœa. It appears to be occasioned by the circulation of non-arterialized blood through the vaso-motor centre, the excitation of which causes contraction of the smaller arteries. The effect of this contraction is to fill the venous system, which becomes still more distended by the obstacle to the onward movement of the blood, presented by the contraction of the expiratory muscles of the trunk and extremities. The heart being abundantly supplied with blood fills rapidly during diastole, and contracts vigorously, in consequence of which, and of the increased resistance in front, the arterial pressure rises. This last effect is, however, temporary: the diastolic intervals being lengthened by the excitation of the inhibitory nervous system, and the heart itself weakened by defect of oxygen, the organ soon passes into a state of diastolic relaxation. Its contractions become more and more ineffectual till they finally cease, leaving the arteries empty, the veins distended, and its own cavities relaxed and full of blood. The heart's contractility is not finally lost, however, nearly as soon as its movements cease; for the action of the right ventricle may be renewed, for some time after it has stopped, by withdrawing a portion of its contents—either through the pulmonary artery, their natural channel—or, more directly, by an opening made in its own parietes, in the auricle, or in the jugular vein. On the other hand, the left ventricle may be again set in action by renewing its appropriate stimulus of arterial blood.* Hence, if the stoppage of the circulation have not been of too long continuance, it may be renewed by artificial respiration;† for the replacement of the carbonic acid by oxygen in the air-cells of the lungs restores the circulation through the pulmonary capillaries; and thus at the same time relieves the distension of the right ventricle, and conveys to the left the due stimulus to its actions. Tracings taken of the blood-pressure in gradually induced Asphyxia exhibit curves, named, after the physiologist who first observed them, Traube's curves, which indicate periodic increase and diminution of the blood-pressure, and are believed to be due either to the rhythmical stimulation of the vaso-motor centres or to the respiratory acts; inspiration favouring the passage of the blood through the capillaries of the lungs, and expiration retarding it.—Of the mode in which the pulmonary circulation is thus stagnated by the want of oxygen, and renewed by its ingress into the lungs, no other consistent explanation can be given than that which is based on the doctrine already laid down in regard to the capillary circulation in general—namely, that the performance of the normal reaction between the blood and the surrounding medium (whether this be air, water, or solid organised tissue) is a condition necessary to the regular movement of the blood through the extreme vessels. That no mechanical impediment to its passage is created (as some have maintained) by the want of distension of the lungs

* Setschenow has made some important researches on the amount and kind of gases contained in the blood of asphyxiated animals (dogs). He found that only traces of oxygen could be discovered in either the venous or arterial blood: the quantity of nitrogen varied from 1 to 2 parts, of free carbonic acid from 28 to 38·8 parts, and of combined carbonic acid from 1·7 to 4 parts (Henle and Meissner, "Bericht," 1859, p. 305).

† Of the two chief modes of performing this operation, Dr. Silvester's method of alternately raising and depressing the arms, 15 or 16 times in the minute, of which Dr. Bain's is only a modification, appears to be far preferable to Dr. Marshall Hall's method of rotating the body half over, and pressing on its chest. See Marshall Hall's work on "Drowning," "Med. Times and Gaz.," 1858, vol. i. pp. 147, 176, *et seq.*, and "Med. Chir. Transact.," vol. liii. 1870, p. 291.

has been fully proved by the experiments of Dr. J. Reid, on the induction of Asphyxia by the respiration of nitrogen; at the same time it must be admitted that the contraction of the smaller arteries is a very important factor in the arrest of the circulation in the pulmonary capillaries of the lungs, since it is in accordance with what is elsewhere seen when the vaso-motor centres are stimulated, and is very certainly deducible from the phenomena of pressure observed in the arteries and veins respectively.*

301. It is obvious that by the repeated passage of the same air through the lungs, it must, though originally pure and wholesome, become so strongly impregnated with carbonic acid, and must lose so much of its oxygen, as to be rendered utterly unfit for the continued maintenance of the aërating process; so that the individual who continues to respire it shortly becomes asphyxiated. There are several well-known cases, in which the speedy death of a number of persons confined together has resulted from neglect of the most ordinary precautions for supplying them with air. That of the "Black Hole of Calcutta," which occurred in 1756, has acquired an unenviable pre-eminence, owing to the very large proportion of the prisoners—123 out of 146—who died during *one night's* confinement in a room 18 feet square, only provided with two small windows; and it is remarkable that of the 23 who were found alive in the morning, many were subsequently cut off by "putrid fever." Such catastrophes have occurred even in this country, from time to time, though usually upon a smaller scale; there has happened one at no distant date, however, which rivalled it in magnitude. On the night of the first of December, 1848, the deck passengers on board the Irish steamer "Londonderry" were ordered below by the Captain, on account of the stormy character of the weather; and although they were crowded into a cabin far too small for their accommodation, the hatches were closed down upon them. The consequence of this was, that, out of 150 individuals, no fewer than 70 were suffocated before the morning.†

302. The determination of the cubic space which ought to be allowed for each person in workhouses, schools, and prisons, is a subject of great practical importance. It is to be borne in mind that it is not sufficient for health that a room should contain the quantity of air requisite for the support of its inhabitants during a given time only, since after they have remained in it but a part of that time, the amount of carbonic acid and other products of disintegration which its atmosphere will contain will be large enough to interfere greatly with the due aëration of their blood; but care ought to be taken that the air is renewed so frequently that the amount of carbonic acid gas does not exceed at most one part per 1000. A small room with several people in it may be better ventilated than a larger one with few inhabitants, if the provision

* For a fuller discussion of the pathology of Asphyxia, see the "Cyclop. of Anat. and Phys.," art. 'Asphyxia,' by Prof. Alison; the "Library of Practical Medicine," vol. iii., art. 'Asphyxia,' by the Author; Experimental Essays, by Dr. J. Reid, 'On the Order of Succession in which the Vital Actions are arrested in Asphyxia,' in the "Edinb. Med. and Surg. Journ.," 1841, and in his "Anat., Physiol., and Pathol. Researches;" and the Experimental Inquiry by Mr. Erichsen, in the "Edinb. Med. and Surg. Journ.," 1845.

† In Friedländer's experiments, when an animal (rabbit) was confined in a room containing a full supply of oxygen, but in which the CO_2 produced by its own respiration is allowed to accumulate, dyspnœa gradually supervened, becoming very noticeable in the course of an hour, when the amount of CO_2 reached 9 per cent. After six hours, when the proportion of CO_2 reached 30 per cent., the voluntary and respiratory movements were perceptibly weaker, and in 11 hours the respirations were only 18 per min. After 12 hours, when the amount of CO_2 had risen to 42 per cent., the animal ceased to breathe, though the heart was still beating rhythmically, and the peristaltic action of the intestines continued. (Friedländer and Herter, op. cit.)

for the renewal of the air in it be superior; and it is fortunate that a considerable amount of fresh air is introduced into all houses of modern construction by what may be termed spontaneous ventilation, as distinguished from the special arrangements made by builders and architects. This spontaneous ventilation is effected through the crevices of the doors and windows, especially when open fireplaces are used as in England, and Pettenkofer* has shown that a large and hitherto unsuspected interchange of air takes place even through the walls. Thus, in one case where the room had brick walls, and its size was 2650 cubic feet, with a difference of temperature of 34° F. (66° F. in, and 32° outside), the contents of the room changed once in one hour, a quantity of air equal to 2650 feet entering it in that time. With the same difference of temperature, but with a good fire in the stove, the communication of which with the chimney was made as free as possible, the change of the air rose to 3320 cub. feet, or about 25 per cent. When all openings, crevices in windows and doors, were thoroughly pasted up, there was still a change of 1060 feet per hour. With a difference of temperature of 7° F. (71° in, and 64° outside) the change amounted to 780 cubic feet only per hour, and when a window of 8 feet square was opened the change rose to 1060 feet per hour. These quantities are instructive: they show that a difference of temperature of 34° with carefully shut openings and crevices, is of greater influence than large communications with the outer air at a small difference of temperature, and that a large ward or room with one fireplace is not necessarily well ventilated. Pettenkofer found that in one of his rooms when the difference of temperature between the inside and outside was 9°·5 F. the spontaneous ventilation through each square yard of the wall amounted to about 7 cubic feet, or 43 gallons per hour. The material of which the wall is constructed of course exerts a great influence on the spontaneous ventilation; thus, Märker and Schultze found in their researches on the spontaneous ventilation of stables, that for one square yard of free wall at 9°·5 F. difference of temperature, the spontaneous ventilation amounted per hour—with walls of sandstone to 4·7 cub. feet, of quarried limestone to 6·5, of brick to 7·9, of tufaceous limestone to 10·1, and of mud to 14·4 cub. feet. The renewal of air should, if possible, be so regulated that no draught or sensation of air in motion is experienced. The observations of Pettenkofer and Voit made in their great apparatus at Munich show that no resistance or sense of coolness is felt at ordinary temperature if the hand be moved at a less rate than 19 inches per second, and that as a rule the motion of the air is only felt distinctly when it amounts to $3\frac{1}{4}$ feet per second. The average velocity of the air as measured by the anemometer in this climate is about 10 feet per second, which would make about 7 miles per hour; consequently in one second about 90 cubic feet, in one minute 5400 cubic feet, and in one hour 324,000 cubic feet of air flow over one person in the open. In experiments made in France in connection with the construction of the Hôpital Lariboisière, with a ventilation of 350 cub. feet per bed per hour, the smell was so bad, that the authorities at once directed the quantity to be doubled; but then also the state of air was anything but desirable, and it was only when the amount reached 2120 cubic feet per hour that the air was found to be free from perceptible taint. Pettenkofer and Voit therefore conclude that this amount of fresh air per bed per hour, representing 1-160th of the air flowing over the body in the open, is necessary for the due ventilation of hospitals, schoolrooms, &c.

* See three Lectures entitled "The Air in relation to Clothing, Dwelling, and Soil," delivered before the Albert Society of Dresden, and translated by Aug. Hess, M.D. 1874.

Pettenkofer and Voit* found that no discomfort was experienced from long exposure to an atmosphere containing 10 parts of carbonic acid in 1000 parts, providing this had been added to the air in a pure state; but if the same quantity were present as a result of the respiration of several people, serious inconvenience was soon felt; and similarly Dr. Snow observed that the presence of carbonic acid in the atmosphere acts more deleteriously upon the system in proportion as the normal quantity of oxygen is reduced. Thus, various birds and mammals introduced into an atmosphere containing only from 10½-16 per cent. of oxygen soon died, although means were taken to remove the carbonic acid set free by their respiration as fast as it was formed, whilst an increase in the proportion of carbonic acid to 12 or even 20 per cent.—the per-centage of oxygen being kept to its regular standard of 21 per cent.—did not appear to enfeeble the vital actions more rapidly than did the reduction of the oxygen in the experiments just referred to. Bernard† moreover found that a bird which lay exhausted from breathing in a limited quantity of air, recovered itself when the carbonic acid was partially absorbed by caustic potash. He observed also that the circulation of blood charged with carbonic acid rapidly arrested the activity of the secretory organs, as the kidneys, which recommenced to discharge their function as soon as oxygenated blood was allowed to pass through them. The proportion of carbonic acid present in the air of large towns has been examined by Dr. Roscoe,‡ by Dr. Angus Smith,§ and by Mr. Leigh.‖ Dr. Roscoe found the usual proportion of carbonic acid in the air of London to be 3·7 parts in 10,000; whilst the proportion in Manchester, according to Dr. Smith, was 12 parts in 10,000, on a still day, and from 4·5 to 8 parts in 10,000 on a windy day. From experiments made with permanganate of potash, he ascertained that on the high grounds north of Manchester there existed but 1 grain of organic matter in 200,000 cubic inches of air, whilst in close places in the town there was 1 grain in 8000 cubic inches. According to Braconnot,¶ the black particles always floating in the atmosphere of large towns consist chiefly of carbon, bitumen, and sulphate of ammonia. Mr. Leigh finds a small quantity of sulphuretted hydrogen in the air of Manchester. The air of sewers, and generally air loaded with organic matters, has an alkaline reaction, from the presence of ammonia and ammonium-sulphide. The average amount of CO_2 gas in the wards of London hospitals was found by Smith to be on the average 0·0781 per cent.; after midnight it rose to 0·1044, and in an overcrowded theatre it was 0·32. In New York Endemans** found: in the prisons of New York 0·083–0·152; warehouses with closed windows, 0·147–0·167; schools, both with closed and open windows, about 0·097. Theatre when full: parterre, 0·130–0·298; gallery, 0·365–0·406 per cent. The presence of a certain proportion of aqueous vapour seems to be requisite for health. F. Falk†† found that small animals, as rabbits, kept in air from which all watery vapour was withdrawn, by means of sulphuric acid and calcium chloride, soon began to breathe with difficulty, and were frequently affected by epileptic attacks; and Sanders‡‡ attributes the peculiarities of the Americans, both in mind and body, their nervous

* An abstract of these observations will be found in the "Med. Times and Gazette" for 1862, p. 459.

excitability, their weight, and the more rapid consumption of their vital powers to the dryness of the air in America, the prevailing s.w. wind blowing over a wide expanse of country. In Falk's experiments the saturation of the air with watery vapour produced no ill effects.

303. It appears that in all climates, and under all conditions of life, the *purity of the atmosphere* habitually respired is essential to the maintenance of that power of resisting disease, which, even more than the ordinary state of health, is a measure of the real vigour of the system. For, owing to the extraordinary capability which the human body possesses of accommodating itself to circumstances, it not unfrequently happens that individuals continue for years to breathe a most unwholesome atmosphere, without apparently suffering from it; and thus, when they at last succumb to some epidemic disease, their death is attributed solely to the latter; the previous preparation of their bodies for the reception and development of zymotic poison being altogether overlooked. It is impossible, however, for any one who carefully examines the evidence, to hesitate for a moment in the conclusion, that the fatality of Epidemics is almost invariably in precise proportion to the degree in which an impure atmosphere has been habitually respired; that an atmosphere loaded with putrescent miasmata may afford a *nidus* wherein a zymotic poison undergoes a marked increase in quantity and intensity, the putrescent exhalations from the lungs and skin of the living subject being at least as effectual in furnishing such a 'nidus,' as are the emanations from fæcal discharges or from other decomposing matters; that the habitual respiration of such an atmosphere tends to produce a condition of the blood which renders it peculiarly susceptible of perversion by the introduction of zymotic poisons, and which favours their multiplication within the system; and lastly, that by due attention to the various means of promoting atmospheric purity, and especially by efficient ventilation and sewerage, the rate of mortality may be enormously decreased, the amount and severity of sickness lowered in at least an equal proportion, and the fatality of Epidemics almost completely annihilated. The effects of good drainage and water-supply have been recently well exemplified in the case of Salisbury: the average number of deaths for the eight years preceding the completion of the drainage in this town (excluding the Cholera year) having been 27 in 1000, and for the same period since, 21 in 1000; an actual reduction of almost one-fourth of the whole number.* And it cannot be too strongly borne in mind, that the efficacy of such *preventive* measures has been most fully substantiated, in regard to many of the very diseases in which the *curative* power of medical treatment has seemed most doubtful; as, for example, in Cholera and Malignant Fevers.—The practical importance of this subject may be estimated from the startling fact, which inquiries prosecuted under the direction of the Board of Health have brought to light†—viz., that the *difference* in the annual rates of mortality, between the most healthy and the most unhealthy localities in England, amounting to no less than 34 in 1000, is almost entirely due to Zymotic diseases, which might be nearly (if not completely) exterminated by well-devised sanitary arrangements. The *lowest* actual mortality is 11 per 1000, while the *highest* is 45 per 1000; and between these extremes there is every intermediate degree of range. But what may be termed the *inevitable* mortality, arising from diseases which

* See "Times," Oct. 24, 1863.

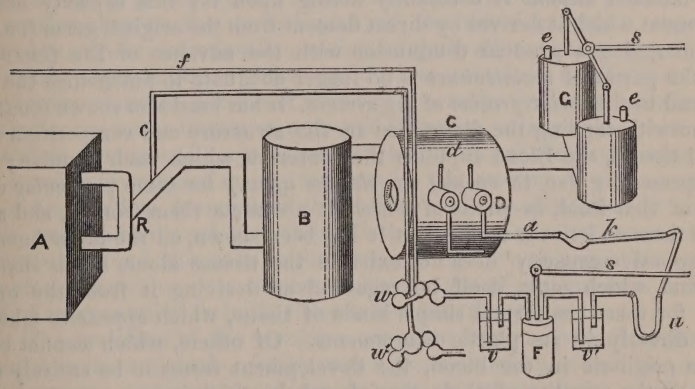
† See "Summary of Experience on Disease, and Comparative Rates of Mortality," by William Lee, Superintending Inspector, 1851. Nearly similar numbers are to be found in the "Twenty-ninth Annual Report of the Registrar-General," 1868. Of 13 large towns, the mortality of Liverpool was the highest (42 per 1000); that of Birmingham and Hull the lowest, 24 per 1000.

would not be directly affected by Sanitary improvements, is a *nearly constant* quantity throughout—namely, the 11 per 1000 of those districts which are free from Zymotic disease. The average mortality of all England, in ordinary years, is about 22 per 1000, or just double that to which it might be reduced; so that, taking the population of England and Wales (as by the last Census) at 20 millions, the average annual mortality must be 440,000, of which only 220,000 is *inevitable*, an equal amount being *preventable*.

Pettenkofer's Respiration Apparatus.

The construction of Pettenkofer's apparatus, with which so many important investigations have been made, may here be briefly given. A full description illustrated by three plates is given in the "Physiologische Chemie" of v. Gorup-Besanez. It consists essentially of a sheet-iron chamber (A), containing table, chair, and bed, from which the air is slowly exhausted by two pumps (G), worked by a small steam-engine. Fresh supplies of air are admitted through ventilators. The greater part of the air is drawn through R, and is conducted into a large receptacle (B) filled with wet pumice-stone in order to saturate it with aqueous vapour, and then enters the gasometer, where its volume is measured. From this it

Fig. 170.



is drawn by the suction of the pumps, and having passed through them escapes into the air. For the analysis of the air in the immediate vicinity of the chamber a tube (*f*) conducts a certain quantity of air which, by means of a mercurial exhausting and pressure pump (F), is drawn through the bulb apparatus containing sulphuric acid (*w*); it is then made to pass through an inspiratory mercurial valve (*v*) into F, then through a similarly constructed expiratory valve (*v'*) into the U-shaped tube (*u*), in which it is saturated with watery vapour by means of moistened pumice-stone. It is then propelled through the tube (*k*) filled with baryta water, by which the amount of carbonic acid gas present is determined. It then passes through the small meter (D), where its volume is determined, and it is finally discharged into the air through the small tube (*d*). For the analysis of the air, contaminated with the cutaneous and pulmonary excretion of the subject of the experiment, a small tube (*c*) is attached to the main discharge tube (R); the air thus obtained is conducted through a series of apparatus which is the precise duplicate of that just described, enabling an exact comparison to be instituted. The accuracy of the whole method of investigation was ascertained by control experiments with wax candles, the products of the combustion of which were compared with the amount that direct analysis showed ought to have been obtained. The average error for the carbonic acid did not exceed 0·3 per cent., and for the water 1·5 per cent. for 24 hours.

CHAPTER X.

OF NUTRITION.

1. *General Considerations.—Formative Power of Individual Parts.*

304. The function of Nutrition, considered in the widest acceptation of the term, includes that whole series of operations by which the alimentary materials—prepared by the digestive process, introduced into the system by Absorption, and carried into its *penetralia* by the Circulation—are converted into Organized tissue; but in a more limited sense it may be understood as referring to the last of these operations only—that of *Histogenesis*, or tissue-formation, to which all the other organic functions, in so far as they are concerned in maintaining the life of the individual, are subservient, by preparing and keeping in the requisite state of purity the materials at the expense of which it takes place. Every integral part of the living body possesses a certain capacity for growth and development, in virtue of which it passes through a series of successive phases, under the influence of the steady Heat, which in the warm-blooded animal is constantly acting upon it; this capacity being an endowment which it derives by direct descent from the original germ (CHAP. I.), but undergoing a gradual diminution with the advance of life (CHAP. XX.), until the power of *maintenance* is no longer adequate to antagonize the forces that tend to the *disintegration* of the system. It has been also shown (CHAP. VII.) that, notwithstanding the diversities in the structure and composition of the several tissues, the Blood supplies the materials which each require; every tissue possessing (so to speak) an *elective affinity* for some particular constituents of that fluid, in virtue of which it abstracts them from it, and appropriates them to its own uses.—But it has been shown, on the other hand, that the 'formative capacity' does not exist in the tissues alone, but is shared by the Blood, which must itself be regarded as deriving it from the original germ; for there are certain simple kinds of tissue, which appear to take their origin directly in its plastic components. Of others, which cannot be said thus to originate in the blood, the development seems to be entirely determined by the quantity of their special *pabula* which it may contain. Thus, an increase of Adipose tissue takes place, when the blood habitually includes an unusual amount of fat; an augmentation in the proportion of the Red Corpuscles of the blood may be distinctly observed (especially if it has been previously diminished unduly) when an additional supply of iron is afforded; and when one of the Kidneys has been removed, or is prevented by disease from performing its normal function, the other, if it remain healthy, undergoes an extraordinary increase in size, so as to perform the duty of both organs, the augmented development of its secreting structure being here also fairly attributable to the accumulation of its appropriate materials in the blood.* Even of those tissues which must be considered as most independent

* This principle is one most fertile in Pathological applications; for there can be little doubt that the development of many morbid growths is due, not so much to a perverted local action, as to the presence of certain morbid matters in the blood, which determines the formation of tissues that use them as their appropriate pabulum. Such is pretty obviously the case with those disorders, which (like the Exanthemata) are universally admitted to be of 'constitutional' character, and which are distinctly traceable to a poison introduced through the blood, whose first influence is exerted in modifying the physical and vital properties of that fluid: and the evidence has been of late accumulating, that it is true also of the various forms of Cancer, the local development of an abnormal structure being in this case also nothing else than the manifestation of the existence of that peculiar matter in the blood,

and self-sustaining, the development is not only checked by the want of a due supply of their appropriate materials, but it is modified in a very remarkable degree by the presence of abnormal substances in the blood, which single out particular parts, and effect determinate alterations in their nutrition, in such a constant manner as to show the existence of a very peculiar 'elective affinity' between them.—In so far, then, as the process of Nutrition is dependent upon the due supply and normal state of the Blood, its conditions have been already sufficiently discussed; and we have now only to consider it in its relations to the Tissues.

305. The demand for Nutrition primarily arises from the tendency of the organism to simple *Increase* or *Growth*. Of this we have the most characteristic illustration in the multiplication of the first embryonic cell by the simple process of "duplicative subdivision;" whereby a multitude of cells is produced, every one of which is similar in all essential particulars to the original. But after the different parts of this homogeneous embryonic mass have taken upon themselves their respective modes of development, so as to generate a diversity of tissues and organs, each one of these continues to increase after its own plan; and thus the child becomes the adult with comparatively little change but that of growth (CHAP. XVIII. SECT. 4). An excess of growth, taking place conformably to the normal plan of the tissue or organ, constitutes *Hypertrophy;* whilst a diminution, without degeneration or alteration of structure, is that which is properly distinguished as *Atrophy*.—But Growth is not confined to the period of increase of the body generally; for it may manifest itself in particular organs or tissues, as a normal operation, at any subsequent part of life; as when an extraordinary demand for the functional activity of a particular set of muscles is supplied by an increase in the amount of their contractile tissue.—And further, even where there is no such manifestation of increase, there is really a continual growth in all the tissues actively concerned in the vital operations, and this even to the very end of life; although it may be so far counterbalanced, or even surpassed, by changes of an opposite kind, that instead of augmentation in bulk, there is absolute diminution.

306. The evolution of the complete organism from its germ, however, does not consist in mere growth; for by such a process nothing would be produced but an enormous aggregation of simple cells, possessing little or no mutual dependence, like those which constitute the shapeless masses of the lowest Algæ. In addition to increase there must be *Development*—that is, a passage to a higher condition, both of form and structure; so that the part in which this change takes place becomes fitted for some special function, and is advanced towards the state in which it exists in the highest or most completed form of its specific type. Thus the development of *tissue* consists in the change from a simple mass of cells or fibres into any other form; as in the production of Dentine from the cellular substance of the tooth-pulp, or in the formation of Bone in the sub-periosteal membranes. So, again, the developmental change is seen in the passage of an entire *organ* from a lower to a higher condition, by the evolution of new parts, or by a change in the relations of those already existing, even though the change in its texture should consist of little else than of simple increase: thus, in the development of the heart, we have the original single cavity subdivided, first into two, and at last into four chambers; and in

which is the appropriate nutriment of its component tissues; or, as Mr. Simon appropriately designates it, "a new excretory organ, which tends essentially to acts of eliminative secretion, just as distinctly as the healthy liver or the healthy kidney."—See Mr. Simon's "Lectures on General Pathology," pp. 87, 152; and Sir James Paget's "Lectures on Surgical Pathology."

the development of the Brain, we find the sensory ganglia to be the parts first formed, the anterior lobes of the cerebrum to be evolved (as it were) from these, the middle lobes sprouting forth from the back of the anterior, and the posterior from the back of the middle: yet, with all this, there is no production of any new kind of tissue, the new parts being generated at the expense of histological components identical with those of the pre-existing.—Now it is in the early period of embryonic life that the *developmental* process is most remarkably displayed; for it is then that we see that transformation of the primordial cells into tissues of various kinds, which originates a special *nisus* in each part, whereby the production of the same tissue, in continuity with that first formed, comes to be a simple act of growth: and it is then also that we observe that marking out of all the principal organs, by the development of tissue in particular directions, which makes all subsequent evolution but a completion or filling-up of the plan thus sketched out. Thus, during the first days of incubation in the Chick, the foundation is laid of the vertebral column, the nervous centres, the organs of sense, the heart and circulating system, the alimentary canal, the respiratory apparatus, the liver, the kidneys, and many other parts; and at the termination of that period, the chick emerges in such a state of completeness of development, that little else than *increase* is wanting, save in the plumage and sexual organs, to raise it to its perfect type. The same may be said of the Human organism; save that the period of its development is relatively longer, in accordance with the higher grade which it is ultimately to attain; its earliest stages being passed through, however, with extraordinary rapidity. The complete evolution of the generative organs, of the osseous skeleton, and of the teeth, constitute the principal developmental changes which the Human organism undergoes in its progress from the infantile to the adult condition: almost every other alteration consisting in simple increase of its several component tissues and organs, without any essential change in their form or structure. And when the adult type has been once completely attained, every subsequent change is one rather of degeneration than of development, of retrogression rather than that of advance.

307. The difference between these two processes of Growth and Development is most characteristically shown in those cases in which there is a partial or complete arrest of one of them, without any corresponding impairment of the other. Thus a dwarf, however small in stature, may present a perfect development of every part that is characteristic of the complete human organism; the deficiency being solely in the capacity for *growth*. On the other hand, the usual size at birth may be attained, and every organ may present its ordinary dimensions, and yet some important part may be found in a condition of *arrested development;* thus the Heart may consist of a single cavity, or the inter-ventricular or inter-auricular septa may be incomplete, so that the organ has not passed beyond the grade of development which it had attained at an early period of embryonic life, although its growth may have continued; or the Brain may in like manner exhibit a deficiency of the posterior lobes, or of the corpus callosum, or of some other part whose formation normally takes place in the latter month of intra-uterine life, although the parts already produced may have continued to grow at their usual rate.—Numerous instances of the same kind might be cited, but these must suffice.

308. The demand for nutrition arises, however, not merely from the exercise of the formative powers which are concerned in the building-up of the organism, but also from the degeneration and decay which are continually taking place in almost every part of it, and the effects of which, if not

antagonized, would speedily show themselves in its complete disintegration. As each component cell of the organism has to a certain degree an independent life of its own, so has it also a limited duration; and its duration usually bears an inverse ratio to its functional activity. This is particularly striking when we compare the ratio of change in the organisms of cold-blooded animals at low and at high temperatures; for they live slowly, need little nutriment, give off but a small amount of excretory products, and require a long time for the performance of the reparative processes, under the former condition; but live fast, require a comparatively large supply of nutriment, give off a far greater amount of carbonic acid and other excretions resulting from the "waste" of tissue, and exhibit a far more rapid reparation of injuries, in the latter state. The constantly high temperature of Man, as of other warm-blooded animals, prevents this difference from being displayed in him in a similar manner; but it is well seen when we contrast his different tissues with each other, and study their respective histories. For whilst there are some (I.) which appear to pass through all their stages of growth, maturation, and decline, within a limited period, there are others (II.) whose existence seems capable of almost indefinite prolongation, and others, (III.) again, which are liable to have a period put to their life at any time, by the direction of their vital force into other channels.

I. Of those belonging to the first category, which are actively concerned in the purely *vital* operations of the organism, a characteristic example is presented by the Ovule; which, if not fertilized within a limited period after its maturation, speedily declines and decays; and the same law of limited duration doubtless extends to a large proportion of such tissues as are actively concerned in the maintenance of the organic functions; as, for example, the Corpuscles of the blood, the Epithelial cells of many glands which are instrumental in the process of Secretion, the cells forming the parenchyma of the Absorbent and Vascular Glands, and many others.

II. The contrary extreme to this may be found in those tissues whose functions are rather *physical* than vital; and especially in such as undergo consolidation by the deposit of solidifying matter, either in combination with the animal membrane or fibre, or in its interstices. Such tissues are more withdrawn from the general current of vital action; and there seems to be no definite limit to the duration of some of them, except such as is imposed by the chemical and mechanical degradation to which they may be subjected. This appears to be the case with the simple Fibrous tissues, especially the yellow, even in their soft or unconsolidated state; but it is far more obvious in the dentine and enamel of Teeth, which are formed by the combination of calcareous salts with an animal matrix, and which retain their condition apparently unchanged through the whole remainder of life, under circumstances which show that if any nutritive action takes place in them, its amount must be extremely small. In the dentinal structure of the young, however, there is obviously a determinate limit of existence; as is shown by the exuviation, at a certain definite epoch, of the first set of teeth, which exuviation is usually preceded by the death and partial disintegration of their texture. In Hair, Nails, and other Epidermic appendages, again, whose substance, when once it has undergone consolidation by the deposit of horny matter, may remain unchanged for centuries, we must recognise the same principle of indefinite duration, in connection with the cessation of vital activity; the chemical constitution of these textures, moreover, being such as renders them but little prone to be acted upon by ordinary decomposing agencies. The limit of existence seems more determinate, however, in Bone; for not only do we find that, in the first development of this substance, a considerable part of the

tissue originally generated by the consolidation of its osseous or cartilaginou matrix speedily disappears, and that during the whole period of growth of th shaft of a round bone, there is a continual removal of its inner and olde portions, whereby the medullary cavity is progressively enlarged ; but there i strong evidence that, even after the bone has attained its full dimensions a replacement of old Haversian systems by new is continually in progress.

III. In the case of the Muscular and Nervous tissues, however, we trace the operation of causes that differ from any of those already specified. These tissues are doubtless subject, like all others that are distinguished by their vital activity, to the law of limited duration; for we find that, when not called into use, they undergo a gradual disintegration or wasting, which is not adequately repaired by the nutritive processes. But their existence as living structures appears to be terminable at any time, by the exercise of their functional powers; for the development of muscular contractility or of nervous force seems to involve, as its necessary condition, a metamorphosis (so to speak) of the vital power which was previously exercising itself in the nutritive operations; and the materials of these tissues, now reduced to the condition of dead matter, undergo those regressive changes which speedily convert them into excrementitious products. But the very manifestation of their peculiar vital endowments determines an afflux of blood towards the parts thus called into special activity; and from this it comes to pass, that the nutrition of these textures is promoted, instead of being impaired, by the losses to which they are thus subjected; so that their constant exercise occasions an augmentation rather than a diminution of their substance—a due supply of the requisite materials being always presupposed.

309. Thus it comes to pass, that, during the whole period of active life, a demand for Nutrition is created by every exertion of the vital powers, but more especially by the evolution of the Nervous and Muscular forces. The production and application of these, indeed, may be considered as the great end and aim of the Human organism, so far at least as the individual is concerned; the whole apparatus of Organic life being subservient to the building up and maintenance of the Nervo-muscular apparatus, and of those parts of the fabric (*e.g.*, the bones, cartilages, fibrous textures, &c.) which it uses as its mechanical instruments. Thus the activity of all the Organic operations, when once the full measure of growth has been attained, is mainly determined by that of the Animal functions; and as the "rate of life" of all the parts which minister to the former will be proportioned to the energy with which they are called upon to perform their functions, their duration will diminish in the same proportion, and hence occasion will arise for their continual renewal.* But since,

* Such an excellent illustration is afforded by the phenomena of Vegetation, of the doctrines here propounded, that it scarcely appears desirable to pass it by in this place, although it has been elsewhere more fully referred to (PRINC. OF COMP. PHYS., §§ 265, 358). —The leaves of Plants serve, like the absorbing and assimilating cells of Animals, for the introduction and elaboration of the nutritive materials which are to be applied to the extension of the fabric; the more permanent and inactive parts of which are thus generated at the expense of materials prepared by the vital operations of the more transitory and energetic. Now there is an obvious limit to the duration of the leaf-cells; but this limit is not precisely one of *time*, being rather dependent upon the *completion of their series of vital actions*. Thus, although we are accustomed to look upon the 'fall of the leaves' (which is nothing else than an exuviation consequent upon death) as a phenomenon of regular seasonal recurrence, and to regard their replacement by a new growth as occurring at a not less constant interval, yet experience shows that these intervals are entirely regulated by temperature; for if one of the ordinary deciduous trees of temperate climates be transferred to a tropical climate, it will live much faster, its leaves being shed far more frequently, and being replaced much more speedily; so that two, or even three, successive exuviations and reproductions of its foliage may take place within a year.

in the attainment of the adult condition, the productive capacity has undergone a gradual diminution, whilst the exercise of the animal powers has become vastly increased, the formative processes are only capable of *maintaining* the Organism in its state of completeness and vigour by making good the losses consequent upon the continual disintegration to which it is subjected by its nervo-muscular activity. And with the advance of years, the further diminution of the productive capacity involves—on the one hand, a progressive decrease in the substance of the tissues and organs most important to life (their bulk, however, frequently remaining unchanged, or even increasing, in consequence of the accumulation of fat)—and on the other, a gradual weakening of its power of action. (See CHAP. XX.)

310. The performance of the function of Nutrition, the demand for which arises out of the causes that have been now discussed, is dependent, not merely upon a due supply of pure and well-elaborated blood, but also upon the normal condition of the part to be nourished, and especially upon its possession of a right measure of "formative capacity;" in virtue of which the newly-produced tissues are generated in the likeness, as well as in the place, of those which have become effete. The exactness of this replacement is most remarkably shown in the retention of the characteristic form and structure of each separate organ or part of the body, and thus of the entire organism, through a long series of years; no changes being apparent (so long as the state of health is preserved), but such as are conformable to the general type of that alteration which the organism undergoes with the advance of life. And not only is this to be noticed in the conservation of all those distinguishing points of structure which mark the species and are essential to its well-being, but it is still more remarkably displayed in the continuous renewal of those minor peculiarities which constitute the characteristic features of the individual, and which serve to distinguish him from his fellows. And how much this depends upon the formative capacity originally derived from the germ is evident from this, that a similar moulding (so to speak) of the nutritive material takes place, in its original development, at first into the form characteristic of the species, and afterwards into that which marks the individual; and that the peculiarities of the individual are frequently such as have been distinctive of one or other of the parents, or present a combination of both. But it is curious that the formative power should often be exercised, not only in maintaining the original type, but also in keeping up some acquired peculiarity; as, for example, in the perpetuation of a cicatrix left after the healing of a wound. For, as Sir J. Paget has remarked, the tissue of a cicatrix grows and assimilates nutrient material, exactly as do its healthy neighbouring tissues; so that a scar which a child might have said to be as long as his own forefinger will still be as long as his forefinger when he becomes a man. And when the mode of nutrition in any part has been altered by disease, there is frequently an obstinate tendency to the perpetuation of the same alteration; or, if the healthy action be for a time restored, there is a peculiar tendency to the renewal of the morbid process of the part; and this is stronger the more frequently it recurs, until at last it becomes inveterately established. There is, however, in the Tissues generally, as in the Blood, a general tendency to a return to the normal type after it has undergone a temporary perversion; and thus it is that we find the typical structure of parts generally restored when the morbid tendency has been overcome; and that even cicatrices and indurations, notwithstanding their usual obstinate persistence, occasionally disappear. The normal type is, perhaps, less likely to be thus recovered when the departure from it is very slight, and consists rather in the wrong plan (so to speak) on which the

new matter is laid down than in a perversion of the nutritive process itself. It may be useful to conclude this section with a table showing the proportion which the several component parts of the body bear to one another.* It will be seen how large a percentage of the body is composed of the soft tissues, in which rapid processes of disintegration and reconstruction are constantly in course of performance:—

——	Man æt. 33, executed.	Woman æt. 22, killed by accident.	Youth; suicide.	New-born.		Fœtus, sixth month.
				Boy.	Girl.	
Weight of the whole body in grammes	69,668	55,400	35,547	2400	2969	643
Percentage proportion of—						
Skeleton	15·9	15·1	15·6	17·7	15·7	20·3
Muscles	41·8	35·8	44·2	22·9	23·9	22·3
Thoracic Viscera .	1·7	2·4	3·2	3·0	4·5	2·7
Abdominal Viscera .	7·2	8·2	12·6	11·5	12·1	12·3
Fat	18·2	28·2	13·9	20·0	13·5	14·8
Skin	6·9	5·7	6·2		11·3	
Brain	1·9	2·1	3·9	15·8	12·2	18·5

The proportion of water in the body of adults is about 58·5 per cent.; in the new-born child, 66·4 per cent.; the muscles contain 75·7 per cent.; the fat, 29·9; the skin, 72; the blood, 83; the liver, 69·3; and the brain, 75 per cent. of that fluid.

2. *On the Balance of the Vital Economy, or the Relations which subsist between the Ingesta, the Metamorphosis of Tissue, the Work accomplished in and by the Body, and the Ingesta.*†

311. During the last few years many laborious investigations have been undertaken, with a view to determine what may be called the "balance of the vital economy;" or, in other words, to ascertain not only the kind and quality of food requisite to maintain life under varying external conditions, but to gain an insight into the manner in which different kinds of foods are applied to the formation of tissue, the production of mechanical force, and to the maintenance of animal heat; and also the mode in which the results of their metamorphosis within the body are ultimately discharged by the various excretory organs. The average amount of food required by the body has already been given (§ 68), and it has been shown that the ordinary diet of the working man contains between 250 and 300 grains of nitrogen, and between 4000 and 5000 grains of carbon; that he consumes besides about five pints of water and a very variable quantity (200–600 grains) of salts; lastly, that

* From Ranke, "Grundzüge der Physiologie," 1868, p. 143.

Bischoff and Voit, "Die Gesetze der Ernährung des Fleischfressers," Leipzig, 1860. Henneberg and Stohmann, "Beiträge zur Rat. Futterung der Wiederkauer," Braunschweig, 1860. Ranke, "Archiv f. Anat. und Phys.," 1862. Pettenkofer and Voit, "Annal. d. Chemie und Pharmacie," 1862. Schützenberger, "Chimie appliqué à la Physiologie." Seegen, "Sitz.-ber. d. Wien. Akad.," Band lv. lxiii. 1871. Voit in "Zeits. f. Biologie," Band ii. 1866, pp. 6 and 289, Band iii. 1867, p. 1, Band iv. p. 517 ("über Luxus Consumption"), and his experiments either alone or in conjunction with Pettenkofer in the succeeding six volumes of this periodical, which contains numerous other articles on this subject by different workers. See also North, "Urea and Muscular Labour," Foster's "Journal of Physiology," vol. i. p. 171, 1879.—The Editor must here acknowledge his obligations to the standard works of Funke, Ludwig, Vierordt, Budge, Longet, Milne-Edwards, Wundt, Herrman, and Ranke; in each of which, excellent sections on "Nutrition" will be found.

he requires about 11,000 grains of oxygen. These collectively constitute the *Ingesta.* The *Egesta* are represented by the excretions of the Kidneys, Bowels, Lungs, and Skin,* which are composed of the more or less completely oxidized constituents of the food and tissues, as well as, in the case of the alvine evacuations, of the indigestible residue of the food. If the weight of the body remain stationary, the Egesta must necessarily be precisely equal to the Ingesta. But if the quantity of food consumed be greater than necessary, then one of several events may occur: either it fails to be absorbed, and is simply discharged by the bowels, as in an experiment of Ranke, who found that with 64 oz. of meat 22¼ oz. were thus eliminated unaltered; or (as in the case of water and salts) it may be absorbed, and be immediately discharged by the kidneys and skin; or it may be absorbed and be deposited in the body (as often occurs with fat), increasing its weight; or, lastly, it may minister to the performance of more work, and after undergoing oxidation may increase the Egesta generally. If, again, the supply of food be insufficient in quantity, the weight of the body must diminish, the excreta remaining the same, or, the weight of the body being maintained, the excreta must diminish. Speaking generally, increased demand for food and increase of the Egesta are associated with increased activity of the cell-functions throughout the body, which may express themselves in the formation of more abundant secretions, the more rapid circulation of the blood, and the greater energy of the nervo-muscular apparatus. Bidder and Schmidt estimate that the respective amounts of the various digestive fluids which are daily poured into the alimentary canal of an adult Man weighing 14 stone, are nearly as follows:—

	oz.		grains.	
Saliva	56·8	containing	233	of solid matter.
Bile	56·8	„	1208	„
Gastric juice	147·2	„	2976	„
Pancreatic fluid	7·1	„	310	„
Intestinal juice	7·1	„	46	„

So that nearly 10 oz. (*troy*) of solid matter are separated from the blood in the digestive secretions, for the purpose of introducing new alimentary materials of not more than two or three times the amount; and thus we see that a large portion of the food ingested and assimilated must be consumed in providing for the introduction of a further supply, in addition to that which, when duly assimilated, is applied by the nutritive processes to the repair of the solid tissues. All these processes imply the more active absorption of oxygen and a corresponding increase in the excreta, which are essentially products of combustion, so that when the muscles are powerfully exerted, larger quantities of carbonic acid and water are excreted, whilst if the activity of the glands is increased, more urea (containing the chief portion of the nitrogen of the ingesta) is eliminated. It must be understood, however, that it is not owing to the quantity of oxygen absorbed that the general activity of the cells throughout the body is augmented, but the activity of these regulates the amount of oxygen absorbed. This is well shown by the fact that whilst, as Ewald has pointed out, the oxygenation of the Hæmoglobin may be raised to saturation by sufficiently active respiration, this does not lead to any increase in the consumption of oxygen by the economy (Pflüger). To augment the consumption of oxygen, the growth and multiplication and functional activities of the cells of the organism must be increased. These activities are dependent upon the play of molecular forces in the cells—that is to say, upon the entrance

* To which may be added the fluids discharged at certain periods by the Mammary Glands, Testes, and Uterus.

into and exit of nutritive fluids from their interior, and the changes effected by the cells in such fluids and on their own composition. Albumin, when abundantly supplied, augments these changes. Fats and sugars diminish them, and they fall to a minimum in inanition. Voit has with some success endeavoured to establish a distinction between "circulating albumin" and "tissue" or "organ albumin," the former of which supplies the new material required to replace the old in cell-formation, and is much more susceptible of the action of oxygen. He estimates, indeed, that of the tissue-albumin only one per cent. is destroyed, whilst about 70 per cent. of the "circulating albumin" undergoes disintegration. Voit supports his views by a comparison of the amount of albumin decomposed in inanition with that in excessive consumption of meat, in which it may be as much as ten times greater. The following experiment by Pettenkofer may be selected as an example of the mode in which the balance of the Ingesta and Egesta is worked out in the apparatus he has constructed for the purpose, and a description of which has already been given (p. 395).* In considering experiments of this nature, it may be accepted as a fact that all the nitrogen of the food is eliminated by the urine and fæces; the quantity discharged by the lungs and skin (0·6 of a grain in 24 hours) being too small to interfere with the results (Parkes). The subject of the experiment was a strong and lively dog, weighing 33 kilogrammes (or 72 lbs., the kilogramme being 2·2 lbs. avoird.), which was found to maintain its weight nearly unaltered when fed with 1500 grammes (23,160 grains, the gramme being 15·44 grains) of meat per diem; whilst thus fed it absorbed from the air 477·2 grammes (7367 grains) of oxygen. Analysis of the excreta gave the following results:—

Ingesta.		*Egesta.*	
Meat	1500 grammes	Urine	1075·0 grammes.
Oxygen	477·2 „	Fæces	40·7 „
		Carbonic Acid	538·2 „
		Water	354·8 „
		Carburetted Hydrogen	1·6 „
		Hydrogen	1·4 „
	1977·2		2011·7

Analysis of the *Ingesta* showed that—

1500 grammes of meat contained		187·8 grammes	of Carbon.
„ „ „ „		152·45 „	of Hydrogen.
„ „ „ „		51·0 „	of Nitrogen.
„ „ „ „		1089·25 „	of Oxygen.

Of the 1089·25 grammes of Oxygen 77·25 were contained in the dry meat and 10·12 in the water, and of the 152·45 grammes of Hydrogen, 25·95 were contained in the dry meat and 126·50 in the water. In addition, 477·2 of Oxygen were absorbed from the air. The total ingestion of Oxygen was therefore 1566·45 grammes.

Analysis of the *Egesta* showed 1075 grammes of urine, containing, with 152·2 of dry residue, 107·9 grammes of urea and 16·3 grammes of salts. After deducting the urea and salts from the total residue there remained for other urinary constituents 28 grammes, which further analysis showed to contain 9·6 grammes of carbon, 2·5 grammes of hydrogen, and 15·9 of oxygen: 40·7 grammes of moist fæces, which when dried weighed 11·2 grammes, contained 4·9 grammes of carbon, 0·7 of hydrogen, 0·7 of nitrogen, 1·5 of oxygen, and 3·4 grammes of salts. We have thus in the Egesta—

* V. Gorup-Besanez, "Lehrbuch der Physiologischen Chemie," 1875, p. 843.

Carbon	21·6	grammes	contained in the urea.
„	9·6	„	„ in the other constituents of the urine.
„	4·9	„	„ in the fæces.
„	146·7	„	„ in the carbonic acid gas of the pulmonary and cutaneous transpiration.
„	1·2	„	„ in the marsh gas of the pulmonary and cutaneous transpiration.
Total . .	184·0	grammes.	

Hydrogen . . .	7·2	grammes	contained in the urea.
„ . . .	2·5	„	„ in the urinary constituents.
„ . . .	102·5	„	„ in the water of the urea.
„ . . .	0·7	„	„ in the dry fæces.
„ . . .	3·2	„	„ in the water of the fæces.
„ . . .	39·4	„	„ in the water of the transpiration.
„ . . .	0·4	„	„ in the marsh gas of the transpiration.
„ . . .	1·4	„	„ in the hydrogen of the transpiration.
Total . .	157·3	grammes.	

Nitrogen . . .	50·4	grammes	contained in the urine.
„ . . .	0·7	„	„ in the fæces.
Total . .	51·1	grammes.	

Oxygen . . .	28·8	grammes	contained in the urea.
„ . . .	15·9	„	„ in other urinary constituents.
„ . . .	820·3	„	„ in the water of the urine.
„ . . .	1·5	„	„ in the dry fæces.
„ . . .	26·3	„	„ in the water of the fæces.
„ . . .	391·5	„	„ in the carbonic acid of the pulmonary and cutaneous transpiration.
„ . . .	315·4	„	„ in the water of the transpiration.
Total .	1599·7	grammes.	

Salts	16·3	grammes	contained in the urine.
„	3·4	„	„ in the fæces.
Total .	19·7	grammes.	

If the Ingesta and Egesta are now briefly compared, we get the following balance :—

	Ingesta.	*Egesta.*
Carbon	187·8	184·0
Hydrogen	152·5	157·3
Nitrogen	51·0	51·1
Oxygen	1566·4	1599·7
Salts	19·5	19·7
	1977·2	2011·8
Difference	34·6 grammes.	

The excess of the Egesta over the Ingesta is nearly 35 grammes; this amounts to not quite 1 per cent. of the total weight of the Ingesta and Egesta. This excess is believed by Pettenkofer and Voit to be attributable to the excretion of a small quantity of water, which is rendered probable because the excess of oxygen and hydrogen is in the proportion in which they form water, and because if from the actual body weight the mean daily quantity of fæces was deducted, there was an actual diminution in the weight of the animal amounting to 34 grammes. The minus quantity of 3·8 grammes of Carbon they attribute to a small production of fat from the meat. Numerous experiments of a similar nature have been made on the same principle on man and animals by Pettenkofer and Voit. The principal source of error in experiments con-

ducted in this manner lies in the analysis of the flesh administered as food, especially in regard to the nitrogen which it contains. The estimate here taken was that of Voit,* who considered it to contain 3·4 per cent. of nitrogen; but other observers† have found that the proportion varies in the flesh of different animals, or when the composition of the flesh is determined by different methods of analysis, from 2·14 to 5·17 per cent., so that a surplus or a deficit of nitrogen would be found in the excreta according as the one or the other estimate is taken as the average. Another difficulty is in the analysis of the fæces, especially when the experiment is made on one of the herbivora or on an omnivorous animal, on account of the large amount of indigestible material they contain. In the carnivora, on the other hand, the amount of indigestible substances is insignificant. Thus in cats it does not exceed one per cent. (Bidder and Schmidt); in man it amounts to 4–8 per cent. (Valentin, Barrel, Hildersheim), in the pig to 19·9 per cent. (Boussingault), in the cow to 34·4 to per cent. (Boussingault), and in the horse to 40–50 per cent. (Valentin).

312. *Balance of the Economy in Fasting.*—Great interest attaches to the study of the excreta during inanition, for we may be sure, from the care that we elsewhere see to be taken by Nature in the preservation of life, that the animal then lives most economically; for it is, in fact, living upon its own tissues, and no more is consumed than is absolutely requisite for the maintenance of the internal work of the body, which becomes greatly reduced in amount, whilst after the first day or two there is little disposition to external work. The chief objection to this method of determining the minimum quantity of food required and the minimum amount of Egesta discharged from the body is, that soon after the withdrawal of all supplies, the activity of the principal organs, as the liver, pancreas, spleen, glands of intestine, &c., undergoes material diminution. The diminution in the general weight of the body and of the several excreta begins on the very first day of fasting, and continues throughout, though of course, in consequence of the progressively smaller bulk of the body, in a gradually lessening proportion. The most marked alteration in the excreta occurs in the herbivora, since in fasting they live on themselves; in other words, change from a vegetable to an animal diet, and the urine consequently contains for a time an increased proportion of nitrogen. Both in these animals, however, and in carnivora, the amount of urea gradually diminishes with the diminished bulk and lessened external and internal activities. Well-fed animals bear inanition for a longer period than ill-fed ones, —lean young pigeons dying in three days, and after a loss of only a fourth of their weight, whilst old, well-nourished ones live for thirteen days, and do not die till their weight is reduced to one-half. The loss of weight falls very unevenly on different organs, the store of fat, for example, being almost entirely used up, whilst the nerve-centres undergo scarcely any change; from which it would appear that some organs continue to be nourished at the expense of others. Ranke gives the following as the results of an experiment upon himself, in which no food or drink was taken :—

Body weight before the experiment	69,643	grammes.
„ after „	68,513	„
Loss .	1,130	„

* Voit, "Zeits. f. Biologie," Band i. p. 100.

† Nowak, Leube, Siëwert, Petersen, Ritthausen, "Zeitschrift f. Biologie," Band vii. 1871. Seegen, "Wien. Akad. Anzeiger," 1870, p. 230. Schenk, "Sitzungsber. d. k. Akad. zu Wien." Jan. 1870.

The ingesta (*i.e.*, loss of weight of the body) were calculated for twenty-four hours of the second day of total abstinence from the loss of weight of the body :—

Egesta.	N.	C.	*Ingesta.* (Estimated)	N.	C.
17·025 Urea	7·9455	3·5654	50·7 grammes of Albumen . .	8·024	27·796
0.236 Uric acid . .	0·0786	0·0843			
In the respiration . .	0·	180·8500	198·1 grammes of Fat	0·	156·700
Total .	8·024,	184·5		8·024	184·5

The calculated loss of albumin and fat amounted to 248·8 grammes, to which must be added 7·7 grammes of extractives and salts excreted in the urine. The loss of solids amounted to 256·5 grammes; the remainder, therefore—873·5 grammes of the total loss—was water. Seegen,* from the amount of N. eliminated in the urine, found that in a young girl, who, in consequence of stricture of the œsophagus, was only able to swallow about an ounce of milk per diem, the consumption of body albumin, reckoned dry, was about 386 grains per diem, and that, since an excess of water was egested, the blood and tissues must have become poorer in water, or drier. The metamorphoses of the albuminates during fasting, so far as they were represented by the excretory products of the urine, bore the proportion to the normal metamorphosis of 1 : 4 or 1 : 5. It must be borne in mind, however, that we cannot conclude from analysis of egesta in the fasting state, or from calculation based on those analyses of the quantity of albumin or fat actually consumed in the acts of life, that we have obtained accurate data of the minimum required for the maintenance of an animal in its normal state; for numerous experiments have shown, that if the same amount of food be given as will exactly cover egesta in the fasting state, the excretions by skin and lungs, urine and fæces, will exceed that quantity in weight; clearly showing that the animal still consumes a portion of its own body, or, in other words, that more than a minimum is required. According to Bidder and Schmidt, whilst the loss of weight sustained in a cat during inanition is about 2·2 per cent. daily, nearly twice as much, or 4·4 per cent., is required to keep up its weight to the ordinary standard. The most important of the conclusions drawn by Schmidt in regard to the effects of fasting are—1. That whilst the daily quantity of fat undergoing oxidation, in a fasting animal, remains nearly constant; that of the albumin falls in the course of the first two days to one-half, then remains constant for eight days, then falls slowly, and during the last two days diminishes rapidly and considerably. 2. The quantity of expired aqueous vapour diminishes continually, but unequally, falling more quickly at the commencement and at the end of the experiment. The proportion of aqueous vapour eliminated by the skin and lungs to that discharged by the urine and fæces remains constant as 10 : 7. The absorption of oxygen is also found to diminish unequally, being much less at the commencement of the period of inanition and towards the close of life. The quantity of oxygen expired as carbonic acid also falls (from 80 to 73 per cent.). On the whole, a fasting animal loses daily 1 per cent. of its body substance, calculated *as free from water*, of which 0·6 is albuminous and 0·4 fat. Bischoff and Voit have made similar series of researches on a dog, after having previously in one experiment fed it well; in a second, after having gradually diminished the amount of food; and in others, after having given it an excessive supply of meat and fat. The general conclusions at which they arrived were, that during inanition the

* Seegen, loc. cit., and abstract in "Lancet," 1871, vol. i. p. 793.

amount of consumption of the animal's own tissue was dependent upon its size; since if it had been previously well fed, it lost more in a given time, and if it had been badly fed, it lost less; living in the latter case, as it were, more economically. And further, the consumption was found to fluctuate between the two chief factors of the body—the muscular tissue and the fat—in such a manner that a very muscular animal consumed more flesh, and a very fat animal more fat; which result is attributable in part to the presence of a greater bulk or mass of the tissue, which is consequently more exposed to the action of the oxygen absorbed, and undergoes a greater amount of disintegration. In the experiment in which the animal had been previously well fed, and with a mean weight of 70 lbs., the proportion of nitrogen to that of carbon eliminated was as 1 : 19; the proportion of nitrogen eliminated per diem for each 1 lb. of body weight being 2·1 grains, and of carbon 40 grains. In a second experiment, where the dog had previously been fed on progressively-diminishing quantities of meat, and weighed 70·7 lbs., the proportion of N. to C. was as 1 : 24, and there were eliminated for each 1 lb. of body weight 1·68 grains of N. and 40 grains of C. In a third experiment, where the dog had been so abundantly fed that its mean weight throughout the experiment was 85 lbs., the proportion of N. to C. was as 1 : 16·3, the quantity of N. eliminated per diem to each 1 lb. of body weight being 1·54 grains, and 25·2 grains of C.—Similar observations have been made by Ranke* on himself; and the influence of diet in Man, in effecting a variation in the composition of the excretions, is well shown in the following Table, based on his experiments:—

	Proportion of Nitrogen to Carbon in the collective excretions of the Skin, Lungs, and Kidneys.	Quantity of Nitrogen excreted per diem for each 1 lb. of body weight, in grains.	Quantity of Carbon excreted per diem for each 1 lb. of body weight, in grains.
With mixed food	1 : 12	1·817	45·7
In inanition	1 : 17	1·000	17·82
With non-nitrogenous food	1 : 25	·788	19·5
With excessive and exclusive meat diet (4 lbs.)	1 : 6	8·670	52·8

Ranke found in his experiments that Man required more carbon, *i.e.*, more fat or starch, in his food to supply the wants of his economy, than appeared to be requisite in the Dog experimented on by Bischoff and Voit; and he further remarks that the quantity of nitrogen appearing in the excreta bears an inverse proportion to the carbon contained in the food: consequently, when the fat or starchy constituents of the food are insufficient, the albuminous constituents of the body are drawn upon or are consumed to maintain the temperature. He found also—1. That the minimum quantity of urea (containing nearly all the nitrogen) is discharged during hunger. 2. That whilst mere increase in the quantity of food, irrespective of its composition, has no effect in increasing the quantity of nitrogen eliminated by the kidneys, an increase in the proportion of nitrogenous diet is followed by an increased discharge of urea, though this does not rise proportionately for 24 hours at least; the effect, however, enduring for some time after the withdrawal of such food. 3. The same holds with regard to uric acid. In fasting animals Voit found the proportion of water in the several organs increased in amount, so that in a starved cat the percentage of water in the muscles was 76·5 per cent., whilst in a well-nourished cat it only amounted to 74·6 per cent.; and Ranke found that in the muscles of Frogs in winter, when they obtained little or no food, the proportion

* Müller's "Archiv," 1852, p. 335, *et seq.*

of water was 83 per cent., whilst in summer, when they were well fed, it was only 79. Such increase of the proportion of water has a powerful effect in exhausting the muscles, and probably also leads to depression of the temperature by interfering with the processes of oxidation.

313. The conclusions arrived at by Bischoff and Voit upon the effect of feeding their Dog on pure meat diet are especially interesting. They found that, in order that the animal should neither lose nor gain in weight, a daily supply of meat equal to from 1-20th to 1-25th of the whole weight of its body was required (a smaller proportion than that found requisite by Bidder and Schmidt in the experiments on the Cat); and that if less than this were supplied, a loss of weight took place in consequence of the animal consuming some of its own flesh and fat; whilst if more than this proportion were supplied, a gain in weight occurred. But to produce a daily increase in weight—a constantly increasing weight—a relatively larger proportion of food was continually required, until at last a maximum was attained; the animal then loathed its food, consumed no more, and rapidly returned to its standard weight. At the same time they found that the quantity of meat which the dog required to cover loss on the one hand, and to form flesh on the other, varied always with the mass of the body. In the well-fed animal, therefore, it required more, in the badly-fed less, to produce the same effect. They further conclude that when large quantities of meat are consumed, the products of its retrogressive metamorphosis take up or combine with the oxygen of the blood, and that thus the fat of the animal is spared; the animal's temperature being sufficiently maintained by the combustion of the secondary products of the disintegration of the albuminous compounds. Each animal has a maximum limit of alimentation, which cannot be passed without inducing disturbance of the general health, and this limit varies for each kind of aliment. It is easily reached in the case of fats and albuminoids, but only with difficulty in the case of fats and water.

314. These results have been verified by Ranke in experiments upon himself, with the exception that he found that he was unable to subsist entirely upon a meat diet, and still less, as Hammond has already shown (§ 62), upon pure albumen. Large supplies of meat with diminution of hydrocarbonaceous compounds invariably diminished the fat of the body. The method of diminishing excessive obesity suggested by Mr. Banting, and which consisted in augmenting the use of flesh and reducing the consumption of farinaceous and oleaginous food to a minimum, is founded, therefore, on strict physiological principles. The economy that is effected by a varied diet, and the immense loss of material that results from restricting man to an exclusively animal diet, have already been fully dwelt upon (CHAP. V.). An extraordinary amount of albumen undergoes disintegration on a pure meat diet. Thus Ranke* found that, whilst a healthy man ordinarily excreted about 570 grains of urea per diem, the amount rose to 1327 grains per diem on a pure flesh diet, and he draws particular attention to the fact, that, so far from the increased excretion of urea being due to augmented muscular work, the first effect of an excessive meat diet is not that of increased strength, but rather a feeling of heaviness and weariness in the muscles, with nervous excitation, often rising to sleeplessness, which he attributes to the accumulation in the blood of the alkaline salts of the meat. The following gives the result by Ranke of an experiment on his own person in Pettenkofer's Respiration Apparatus when consuming as much pure flesh as possible:—

* Ranke, "Grundzüge der Physiologie," 1874, p. 196.

Initial weight . . 72·927 kilogrammes.
Terminal weight . 72·781 „
Difference: a loss of weight of 146 grammes, notwithstanding the large amount of meat consumed.

Ingesta.	N.	C.	*Egesta.*	N.	C.
1832 grammes of meat	62·29	229·36	86·3 grammes of urea	40·28	17·26
70 „ of fat	0·	50·27	1·95 „ of uric acid	0·65	0·70
31 „ of salts			99·0 „ of fæces .	3·26	14·88
3371 c. c. of water.			In the respiration . . .	0·	231·20
			2073 c. c. urine.		
			26·6 grammes of common salt.		

The difference in the amount of N. (= 18·1 grammes in favour of the ingesta,) shows that about 523 grammes of albumen were retained in the body, and in order to cover the egesta about 23 grammes of fat must have been supplied by the body. The result of the addition of fat to the food of a carnivorous animal was found by Bischoff and Voit materially to diminish the disintegration of albuminous compounds, as shown by the diminished elimination of urea, so that only a third or fourth part is required. This is intelligible enough when it is remembered that only a certain quantity of ozonized oxygen is present at any moment in the body, and that, since the hydrocarbons possess a much higher affinity for oxygen than the albuminous compounds, they essentially spare or prevent the disintegration and oxidation of the latter. They do not, however, interfere with the ordinary decomposition and reconstruction of the muscular tissues. But if, with the fat, an increased proportion of meat be given, the proportion of urea also increases, obviously because when much more albuminous material is contained in the blood than is required for the maintenance of the tissues, and especially of the muscles, it undergoes oxidation, and, instead of being applied to the tissues, is used up for the production of heat. Sugar and starch consumed with a meat diet seem to operate in precisely the same manner as fat, except that their action, in combining with oxygen, and thus sparing both the adipose and nitrogenous compounds, is, in consequence of their greater affinity for oxygen, still more marked than fat; and if large quantities of sugar be given with sufficient albumen, a deposition of fat invariably takes place.

315. The differences which exist between Carnivora and Herbivora, in regard to the mode in which the constituents of the Ingesta are distributed through the excretions, are very striking. The first and most remarkable feature of difference between them is the very large proportion which the fæcal discharges of the Herbivora bear to the other excretions, which obviously proceeds from the indigestibility of a large part of the alimentary substances they consume. Of the *water* taken into the alimentary canal or formed within the body, nearly two-thirds pass off with the fæces in the Horse, whilst nearly the whole is absorbed in the Cat; and of that which is absorbed by the Horse, little more than one-seventh passes into the urine, the remainder being exhaled from the lungs and skin; whilst in the Cat, the proportion which passes off by the skin is less than one-sixth of that which is absorbed, the remainder being eliminated by the urine. Of the *carbon* taken into the system, a relatively larger proportion passes off by the lungs in the Horse, while a relatively larger proportion enters the urine in the Cat; this is probably because the great bulk of the carbon in the food of the Horse exists in those non-azotized compounds which can be readily converted by oxygenation into carbonic acid and water, and which consequently yield little or nothing to the urine; whilst those products of the decomposition of albuminous substances which pass into the urine, though especially rich in nitrogen, carry

with them a certain measure of carbon into that excretion. In the case of man, the researches of Pettenkofer and Voit show that with ordinary food 54 per cent. of the *water* discharged from the body is eliminated by the kidneys, 5 per cent. with the fæces, and 41 per cent. by the lungs and skin. The amount of *carbon* discharged per diem on mixed food by the skin and lungs is about 3900 grains, of which 4 per cent. is excreted by the kidneys, 6 per cent. by the bowels, and 90 per cent. by the lungs. The amount of *hydrogen gas* eliminated is small, and the major portion of this element passes away in combination with oxygen as water. The quantity of *nitrogen* varies considerably, but with sufficient mixed diet is equal to 300·6 grains daily. Parkes* finds that of this, 25 grains pass off by the bowels per diem, the remainder being eliminated by the urine. The proportion of the alvine to the total excretion of nitrogen varies from 8·1—11·45 per cent. (Parkes); according to Ranke it is 8 per cent. The amount of *Oxygen* absorbed with sufficient food is 12,845 grains, whilst during fasting it is 14,793 grains. In the fasting state more oxygen is taken up than carbonic acid is eliminated, the proportion being 106 : 100; when food is taken, on the other hand, the proportion of oxygen absorbed to carbonic acid eliminated is as 100 : 90; in the latter case the carbon is derived from the hydrocarbons or carbohydrates in the food, whilst in the former it is derived from the tissues, in which case a much larger amount of oxygen is required, the carbohydrates containing much more oxygen.

316. Thus, then, we see that, throughout life, a continuous interchange of material takes place in the very substance of the tissues, and the new material, derived from without, is being constantly laid down to replace the old and effete substance, which, in the act of developing force in one form or another, undergoes oxidation, and, as we shall hereafter see (CHAP. XI. SECT. 3), is then taken up by the circulating current to be removed by the excretory organs. In the earliest periods of life, how active soever the oxidizing processes may be, the power of the fabric to seize and apply the substances employed as food is superior, and the results are seen in the processes of growth and development. In adult life the balance is more equally preserved, and all the faculties of the body attain their highest state of efficiency. But in old age, with the increasing debility of all the vegetative processes, with diminished capability of absorption, diminished energy and rapidity of the circulating current, with more compact and drier tissues, there comes to be a gradual deficiency in the processes of nutrition, until at length the body ceases to be able to nourish itself, the waste is greater than the supply, and the death of extreme old age may be justly compared, in the wasting oftentimes preceded by the degeneration of the tissues and the gradual failure of the temperature, to death by inanition.

317. Of all the constituents of the body, none are of more complex chemical composition, and undergo more numerous and varied changes, than *Albumin*.† The relations which this substance bears to the living body are of the most important and fundamental character; since, as elsewhere shown, it enters largely into the composition of the muscles, nerves, and glandular structures, whilst it also affords the chief material for the production of the fibrin, and hæmoglobin of the Blood. It appears, however, to be itself entirely destitute of formative capacity; for in no exudation which is purely serous do we ever

* 'On the Elimination of Nitrogen from the Human Body,' "Croonian Lectures," "Lancet," vol. i. 1871.

† The formula given for it by v. Gorup-Besanez being $C_{216}H_{169}N_{27}S_3O_{68}$, and by Theile $C_{143}H_{124}N_{17}S_2O_{46}$.

trace the slightest indication of organization; and its conversion into the various kinds of tissues, therefore, must be entirely due to their own power of appropriating and transforming it after it has undergone assimilation. The great function of the Albumin of the blood, then, is to supply the material for these various transformations; and we accordingly find that whatever other changes the fluid may undergo, whether it loses its fibrin or its red corpuscles, or both, albumin is still present in abundance. Its ultimate source is to be found in the food; but the serous liquid which percolates the tissues of the body may be regarded as a reserve store, to be drawn upon in case of need, furnishing albumin to the blood when it might otherwise be deficient; and thus perhaps it is that abstinence or repeated losses of blood do not produce the degree of depression in the proportion of albumin which might be expected from the very marked reduction they effect in that of the corpuscles. When an excess of Albuminous matter is ingested as food, the injurious effects which might follow the too great augmentation of this constituent of the Blood appear to be averted by the readiness with which it undergoes *retrograde* as well as *progressive* metamorphosis; for, if not speedily subjected to the latter change, it appears in the ceaseless interchange which takes place between the contents of the cells of which the body is composed and the fluids, as the lymph and blood bathing their external surfaces, to be affected by decomposing agencies, and to be eliminated from the system by the excretory apparatus, under the form of urinary and biliary matter. From various considerations it would appear the albuminous compounds in their retrograde metamorphoses are capable of breaking up into two groups of substances, of which one contains the whole of the nitrogen, whilst the other is composed of carbon, hydrogen, and oxygen alone. The former are ultimately eliminated from the body as urea or some analogous compound; the latter are either stored up in the form of fat or are discharged after oxygenation in the form of carbonic acid and water. Of the former series, we know that whilst Leucin ($C_6H_{13}NO_2$), Tyrosin ($C_9H_{11}NO_3$), and Glycin ($C_2H_5NO_2$), can be artificially formed by the action of alkalies or acids upon albumin, or even appear during its spontaneous decomposition; these same substances can also be obtained from various tissues of the body, and are always most abundant in those organs in which interstitial changes are most active, as in the spleen and liver.* From muscular tissue, again, Inosinic Acid ($C_{10}H_{14}N_4O_{11}$), Creatin ($C_4H_9N_3O_2$), and the urinary constituent Creatinin ($C_4H_7N_3O_1$), can be directly obtained. The relation of Inosinic Acid and of Allantoin ($C_4H_6N_4O_3$), found in the urine of women during gestation, and in new-born children, to Uric Acid and Urea, which are the ultimate products of the decomposition of the albuminous compounds, is very intimate; whilst, as regards Creatin, the researches of Sarokow† indicate that during active muscular exertion it is converted into Creatinin, or at all events that, in muscles exhausted by action, a greatly increased proportion of Creatinin is generated; and it is well known that both of them are convertible by chemical agents into Urea.‡ The evidence of the derivation of the fatty compounds from the albuminous substances will be given in the next section, and, like that indicating the origin of the farinaceous and saccharine compounds from them, is chiefly of an indirect nature. In regard to the analogous compound, glycogen, it may be observed that the formation of an amyloid substance is the natural function of the liver, and

* Glycin has not, indeed, been obtained in the separate state, but it enters into the composition of the glycocholic acid of the bile. The further decomposition of leucin in the laboratory by fermentation and oxidizing agents, yields the volatile fatty acids well known to occur in glandular organs and in the blood.

† Virchow's "Archiv," 1863, p. 544.

‡ Fownes' "Chemistry," 1861, p. 670.

there is some reason for believing that this is an intermediate stage of the decomposition of albumin into fat; the formation of the glycogen being accompanied by the simultaneous appearance of highly nitrogenous substances, such as Glycocholic and Taurocholic acids, which have been shown by Liebig to be readily derivable from albumin, the latter containing an important element of albumen, namely, Sulphur. In regard to the albuminous, and, as the experiments of Bischoff and Voit appear to prove, the gelatinous constituents of our food also, it is probable that by far the largest part is applied directly to the formation of tissue, including under this term the contents of gland-cells, whilst a much smaller portion, if indeed there be any, termed the "Luxus consumption" by the Germans, is decomposed in the blood without forming tissue. In both instances a kind of decomposition or disintegration takes place under the influence of oxygen, by which, on the one hand, such compounds as Fibrin, Chondrin, Keratin, Taurin, Glycin, Leucin, Creatin, Creatinin, Guanin, Sarkin, Xanthin, Uric Acid, Urea, &c., are formed, which are, for the most part, discharged by the Urine and Fæces; and on the other, certain fatty or saccharine substances are generated, by the further combustion of which the animal heat is maintained, their ultimate products, consisting of Carbonic Acid and Water, being eliminated chiefly by the skin and lungs.

318. As regards the *fatty constituents* of the body, a large proportion is doubtless derived from the oleaginous compounds consumed in the food, though it is certain that a part may also proceed from the metamorphosis or disintegration of both hydrocarbonaceous and albuminous compounds. Of the fats ingested, a portion, after reduction to the fluid state and minute division, is directly absorbed, whilst a smaller portion appears to be decomposed by the pancreatic juice into the fatty acids and glycerin before absorption. It has been suggested by v. Gorup-Besanez that the fat directly absorbed would, under the influence of the active oxygen and alkaline carbonates of the blood, also soon undergo decomposition into the fatty acids and glycerin, which again, by further oxidation, give rise to formic, propionic, and other acids.* It seems reasonable to suppose that the stearates, oleates, and margarates are directly applied to the formation of adipose tissue.† But that the adipose tissue of an animal does not proceed exclusively from the fats ingested with the food is conclusively shown by the experiments of Lawes and Gilbert,‡ who found that in fattening pigs, for every 100 parts of fat in the food, 400–500 parts of fat were stored up in the body of the animal. The question then arises, Does the excess of fat laid down in the body over the fat ingested proceed from the hydrocarbonaceous or from the albuminous constituents of the food? The experiments of Liebig§ and others upon Bees, showing that if these animals be fed upon pure sugar they are yet able to furnish wax for the comb, and the observations of Boussingault, Lehmann, Groner, and Lawes and Gilbert on ducks, geese, pigs, and oxen, showing that on a diet rich in carbohydrates fat is abundantly formed, and either deposited in the tissues or excreted in the milk or fæces, coupled with the well-known fact that negroes rapidly fatten during the period of cutting the sugar-canes, lead to the conclusion that the

* Schulz, Pflüger's "Archiv," Band xv. 1877, p. 403, has shown that at ordinary temperatures, oxygen, even when pure, has no action on fats; the first traces of carbonic acid gas appear at a temperature of 116° C.

† See Hofmann ("Zeits. f. Biologie," Band viii. p. 153). Radziejewski (Virchow's "Archiv," Band x. liii.) and Subbotin ("Centralblatt," 1870, p. 675) are however opposed to this view, because they found, that, although when certain fats with well-marked chemical properties, as spermaceti, were introduced into the alimentary canal of a dog, they underwent absorption, yet they could not be subsequently detected in the subcutaneous fat.

‡ "Philosoph. Transact.," 1859, p. 543. See also Pettenkofer and Voit, "Zeitschrift f. Biologie," Band ix.

§ Gundlach, Huber, Dumas, and Milne-Edwards.

fat of the body may be derived from the carbohydrates, and this is supported by the observation of Pasteur, that in the alcoholic fermentation of sugar Glycerin is one of the products. Lawes and Gilbert estimate that 2½ parts of starch must be consumed in the food to produce one part of fat, the proportion of sugar required being somewhat larger.* But evidence has also accumulated, showing that the fat of the body may be derived from the albuminous compounds; thus Pettenkofer and Voit found that on very full or excessive meat diet their dog excreted considerably less carbon than he ingested, though the quantities of nitrogen ingested and egested were almost exactly equal, and as the animal gained in weight and fat was deposited in its tissues, there was strong reason for believing that it was due to the separation of a part of the albuminous compounds in the form of fat. Other facts which may be mentioned as tending to prove the same thing are the production of adipocere from muscle: the observations of Blondeau, Hoppe, Kemmerich, and Fleischer, that fat can be deposited during a diet composed mainly of cheese; the formation of fat during the maturing of cheese; and the development of fat in a fasting dog when the animal is slowly poisoned with phosphorus; the experiments of Subbotin showing that bitches secrete milk containing the largest amount of fat when the food has been abundant, though composed essentially of lean meat; the observations of Burdach† upon the eggs of Lymnæus, one of the water snails, showing that in the progress of incubation the fat increases apparently at the expense of the albumen, so that whereas in the early stage the amount of fat is about 7 per 1000 and of albumen about 9·53, in the last stage the amount of fat has increased to about 22 parts, whilst the albumen has fallen to 9·18 in 1000 parts; and lastly, the recent experiments of Pettenkofer and Voit‡ all afford strong support to the view that the fats may be derived from the albuminous compounds, the observations of these investigators appearing to demonstrate that when a sufficient amount of albuminous food is supplied, fat ingested as such is stored up in the body, the carbohydrates burnt to maintain the animal heat being really derived from the disintegration of the albumin, which they estimate yields about 55 per cent. of its weight of fat. The phenomena presented in nerve-cells and muscular tissue during the pathological process of fatty degeneration may also be referred to as supplying additional evidence.—The Fatty matters of the Blood, besides being destined to furnish the contents of the Adipose and Nervous vesicles, appear also to be required in the early stages of the production of cells generally. The principal source of their expenditure, however, is that process of combustion by which the heat of the body is maintained; and the amount deposited in the tissues as fat may be looked upon as the surplus of the quantity ingested that is not thus consumed. The quantity of fatty matter in the blood is liable to sudden augmentation from the introduction of a large quantity furnished at once by the alimentary material; and this excess will continue until the surplus has been eliminated, either by the combustive, the nutritive, or the excretory operations. These last do not ordinarily remove the saponifiable fats from the body; for although the mammary secretion in the female draws off from her blood a large quantity of fatty matter, this is destined, not for its purification, but for the nutrition of her offspring; and cholesterin appears to be the only

* The opponents of the view above given, that fat may be derived from the Carbohydrates, contend that the purely chemical evidence is weak, since only fatty acids, poor in carbon, and *traces* of Glycerin and Glycerides, make their appearance in saccharine fermentations.

† F. W. Burdach, 'De Commut. Subst. Prot. in Adipem "Dissert.," 1853.

‡ "Zeits. f. Biologie," Band ix. Heft 1. Weiske und Wildt, "Zeits. f. Biologie," Band x. 1874, p. 1.

fatty substance which is normally excreted for the purpose of being removed from the body. The quantity of fat contained in different parts of the body varies considerably, but it is almost universally present. The blood usually contains about 0·4 per cent., the muscles 3·3, milk 4·3, brain 8, the nerves 22, and adipose tissue 83 per cent. The ultimate disposal of the *saccharine constituents* of the body, which appear to be partly derived from without, and to be partly the result of the decomposition of the albuminous constituents of the blood, as will be hereafter more fully considered (Glycogeny), is still unknown; though there seems to be some probability in favour of their being first converted into Lactic acid, and finally into Carbonic acid and Water, and as these are more easily oxidized than the fats, they spare the latter from combustion.

319. The uses of the various Inorganic compounds, which, as being uniformly present in the Blood, must be considered among its integral constituents, have already been pointed out (§ 58), and it need only here be remarked that the observations of Weiske* show that the bones retain their hold of the salts that enter into their composition with great tenacity, so that if food be supplied in which the proper salts are defective, no material difference can be detected for a considerable period in the composition of the osseous tissue. Papillon† has demonstrated that the Bones contain a large proportion of strontium phosphate, or of magnesian phosphate, replacing the calcium phosphate, if these salts are liberally given with the food, and providing the calcium phosphate is deficient or altogether absent.

320. We may now proceed briefly to consider what is the amount and nature of the work done in and by the body, and endeavour to ascertain the mode in which the food consumed is applied to the production of that work. It has already been stated that the two principal circumstances occasioning a demand for alimentary material are the supply of the loss caused by the activity of the nervo-muscular apparatus, and the production of the heat requisite to maintain the body at a uniform standard. The actual disintegration of the material substratum of the nervous and muscular tissues during exertion appears to be exceedingly small, since fasting animals, or animals fed on non-nitrogenous diet, can for a considerable period perform severe work without the occurrence of any considerable increase upon the amount of nitrogenous excreta eliminated by the same animals when at rest with the same diet. Yet that the tissues really undergo disintegration during exertion, and that they require appropriate nitrogenous food for the repair of the loss occasioned by their wear and tear, is clearly shown by their incapacity for performing work except for a limited period without such supplies. It is reasonable then to suppose that, whilst a certain small portion of the large store of albuminous and other nutritive material present in the body is applied to the nutrition and repair of the work-performing tissues, a very much larger proportion is applied to the development of the forces of various kinds which are exerted by them. The three principal classes of food—the albuminous, farinaceous, and oleaginous—are all of them composed of easily oxidizable material, and it is conceivable that in the act of combining with oxygen, or rather with ozone, the force may either become directly apparent as heat or electricity, or may, through the agency of muscle-, gland-, or nerve-tissue produce movement, secretion, or thought. We have only indirect means of estimating this last; but the quantity of food required for the mechanical and

* "Zeitschrift für Biologie," vii. pp. 179 and 333.

† "Journal de l'Anatomie," 1873, No. 3; see also, König, "Zeits. f. Biologie," Band x. 1874, p. 68. The statement is contested by Weiske, *ibid.* 1872, Band viii. p. 239.

calorific force developed by the body has been rendered capable of being estimated by the experiments of Frankland, Haughton, and others.

321. According to the observations of Professor Frankland, one gramme (15·44 grains) of purified albumen, when burnt in oxygen, yields 4·998 units of heat. Now each unit of heat can be converted into mechanical force, expressed in kilogrammeters, by multiplying it by the number 423; that is to say, the heat required to raise one kilogramme of water 1° C. if converted into mechanical force would raise 423 kilogrammes one meter in height, or an amount of heat equivalent to 1° C. would be produced by the expenditure of an amount of force equal to the raising of 423 kilogrammes to the height of one meter; hence one gramme of albumen burning in oxygen yields 4·998 + 423 or 2117 kilogrammeters—that is, a force sufficient to raise 2117 kilogrammes to the height of one meter. But it is to be remembered that albumen, in passing through the body, is not so completely oxidized as when burnt in oxygen. It is only reduced to the condition of urea; and Professor Frankland has shown that urea can itself be burnt in oxygen, yielding 2·206 units of heat, which is equal to 934 kilogrammeters of force; and as it is found that one gramme of pure albumen in passing through the body furnishes almost exactly one-third of its weight of urea, the effective force developed in the body by its consumption is obviously less than when it is burnt in oxygen to the extent of the amount of force still produced when one-third of a gramme of urea is burnt in oxygen. Hence the effective force of one gramme of albumen is equivalent to 1803 kilogrammeters.* Fat, on the other hand, is as completely burnt in the body as outside of it, and yields, weight for weight, a much larger amount of effective force than albumin. The following Table contains some of the more important determinations made by Professor Frankland:—

Name of the Food.	Effective energy when one gramme of the different substances named is burnt in Oxygen.					Effective energy when consumed in the body in kilogrammeters.	
	Units of Heat.		Kilogrammeters of Force.		Per-centage of water.	Dry.	Natural state.

322. The amount of work done by the body may be divided into—1. Calorific work; 2. Internal mechanical work, such as is required for the main-

* It must be acknowledged that the estimates of different experimenters in regard to the calorific value of different substances vary considerably. Thus, Franke estimates that the combustion of one gramme of starch produces 5232 units of heat, Ludwig 4568, Dulong 3232, Bischoff and Voit 5100, and Frankland 3941. The warming of one pound of water 1° C. is equivalent to a mechanical force of 1390 foot-pounds.

tenance of the circulation, respiration, digestion, &c.; 3. External mechanical work, expended in the movements of locomotion, lifting and carrying weights, &c.; 4. Mental work. And lastly, in youth, the work of growth. The absolute amount of *heat units* daily produced by an adult of average weight has been estimated by Ranke at 2200 (by Helmholtz at 2700), or sufficient to raise the temperature of 48·4 lbs. from the freezing to the boiling point;* or if converted into mechanical force, it amounts to 930,600 kilogrammeters, which would be sufficient to raise the body of a man weighing 68 kilogrammes (149·6 lbs. av.) through a vertical height of 8·5 miles. This heat is expended in conduction and radiation from the body, in warming the air inhaled, and the water and watery vapour exhaled by the skin, kidneys, and lungs, and in warming the food. Next as regards *internal dynamical* work. Professor Haughton† states that the work done in maintaining the circulation and respiration may be estimated at 133 foot-tons, or 41,180 kilogrammeters (heart = 121 foot-tons, muscles of respiration = 11 foot-tons). The same authority gives as the result of numerous observations on the *external* or daily work of various classes of labourers the mean of 353·75 foot-tons (109,549 kilogrammeters), which corresponds well with the results obtained by Coulomb (330 foot-tons), Lamandé (352 foot-tons), and Playfair (346 foot-tons). The work expended in *growth* may be neglected for the adult; and that exerted in *mental operations*, as already stated, can only be indirectly estimated. From the foregoing calculation it would seem that the entire amount of force expended in maintaining the heat of the body of an adult weighing 150 lbs., and in the performance of his internal and external mechanical work, is 1,044,267 kilogrammeters, of which nine-tenths is expended in maintaining the heat, and the remainder in external and internal dynamical work.‡

323. It may be shown, either from an examination of Frankland's Tables, or by calculating the amount of tissue decomposed to furnish the usual amount of urea, carbonic acid, and water eliminated from the body, that almost exactly the same amount of a million kilogrammeters of force are contained in the food. Thus, on Vierordt's estimate—

120	grammes of albumen, dry	= 213,720	kilogrammeters.
90	„ of fat	= 345,690	„
330	„ of farinaceous compounds . . .	= 536,910	„
		1,096,320	

Or on Voit's estimate§ of 118 grammes of albumin, 56 grammes of fat, and 500 grammes of carbohydrates, we have a rather larger number—

118	grammes of albumin	210,150
50	„ of fat	192,050
500	„ of carbohydrates	894,865
		1,297,065

The close approximation of the experimental with the calculated values is of great interest. It may be objected that a very small margin is left for purely mental operations; but it must be remembered that Professor Haughton's

* "Grundzüge der Physiologie," p. 476, 1868.

† Haughton, Address, delivered at the British Medical Association at Oxford, Aug. 1868. Dr. Andrew Buchanan gives reasons for believing that the force of the heart (Left Ventricle) does not exceed 42·3 foot-tons in the 24 hours. See "Lancet," vol. ii. 1870, p. 665.

‡ Professor Haughton, calculating the amount of heat produced from the amount of Carbonic Acid gas eliminated, as shown in Ranke's experiments, estimates the calorific work at five-sixths, and the internal and external mechanical work at one-sixth of the whole amount of force generated.

§ "Untersuchungen der Kost in einig. öffent Anstalten," 1877.

estimate of 353·75 foot-tons, or 109,549 kilogrammeters, for external or mechanical work is very high, being equivalent to that required to raise the body through one mile of vertical height, or to walking 20·74 miles per diem, which is perhaps three times more than is usually accomplished; and that, under such circumstances, either little mental work would be done, or more food would be required. Supposing only seven miles were walked, 118 foot-tons of force would be required, leaving 236 foot-tons available for mental work; but it must be remembered that both mental work and much of the internal mechanical work are again expended in the body. A part of the mechanical force exerted by the heart is given up as heat from obstructed motion in the capillaries, and will be included in the heat given off from the body; and, although nothing positive can be stated as to the form taken by mental work and nervous action generally, it is highly probable that for the most part this is heat. There is every reason to believe that, although the tissue of the nerves and muscles cannot be built up from alimentary materials destitute of nitrogen, the force which can be exerted by those tissues proceeds both from the disintegration and oxidation of nitrogenous as well as non-nitrogenous substances. At any rate, it has been clearly shown by Professor Haughton that the amount of urea (501 grains) eliminated after severe exercise does not represent the oxidation of a sufficient amount of nitrogenous material to account for the work done; nor is there any remarkable increase in the excretion of urea after severe bodily exertion. Moreover, whilst in carnivorous animals the force must proceed from the oxidation of nitrogenous constituents, since they can be nourished upon lean flesh, in herbivorous animals—and, as Verloren has pointed out, in mature insects, as bees and butterflies—it seems equally evident that the nervo-muscular force is generated from the oxidation of farinaceous compounds; and an examination of the excreta gives additional testimony to the same effect. Thus, Professor Haughton found the daily elimination of urea in a Bengal tiger to be 4375 grains, whilst in a sheep it was only 256 grains. It has also been shown by the same observer that in diabetes, where sugar is eliminated by the urine, instead of undergoing combustion, and being discharged from the body in the form of carbonic acid and water, an increased quantity of food is required, which is accompanied by an increased discharge of urea, showing that the nitrogenous materials are consumed to maintain the temperature and to furnish the force required for work, which is always small. Heaton suggests that the whole, or nearly the whole, of the force of the body is generated in the blood, and that Mayer was perfectly right in saying that the muscle produces mechanical effect at the expense of the chemical action occurring in its capillary vessels. It is probable, however, that the oxidising processes take place essentially in the tissues and intertextural fluids.

324. Of the mode in which the substitution of new tissue for that which has become effete is effected in the process of Nutrition, our knowledge is at present limited; but there can be little doubt that it nearly always takes place in a manner closely conformable to the first development of each tissue. In some instances there is an obvious *replacement* of the old and dead by the young and active elements; this is the case, for example, in the constantly-repeated production of the Epidermic and Epithelial layers; for whether they are developed from germs embedded in the subjacent basement-membrane, or from nuclei formed *de novo* in the blastema on its free surface, or by the duplicative subdivision of pre-existing cells, there is a continual succession of new cells, which takes the place of those that are cast off as defunct and useless. So in the growth of Hair, the increase of which takes places only at its base,

re can trace at any period the same development of newly-formed spheroidal ells into horny fusiform fibres, as that which occurred when first the hair egan to sprout from the aggregation of epidermic cells at the bottom of its ollicle. So, again, in the vesicular tissue which constitutes the essential part f the Nervous centres, there are appearances which indicate that its peculiar ells are in a state of continual development, newly-formed ganglionic vesicles aking the place of those which have undergone disintegration. But there re other textures, whose nutrition is more completely *interstitial;* their lements being more closely coherent, and their newly-formed portions being eveloped throughout the substance of the old, instead of (as in the case of the pidermis and its appendages) *superficially* or in mere continuity with it. uch is the case, for example, with Muscle, the mode of whose nutrition has ot yet been elucidated. We can only infer from analogy, that here too each ibre or fibril will pass, in the course of its development, through the same tages which those of the embryo did when its muscles were first formed. And his analogy seems to derive support from the presence, in all well-nourished nuscles, of nuclei; for these, as Sir J. Paget remarks, "are not the loitering mpotent remains of embryonic tissue, but germs or organs of power for new ormation." And it is further confirmatory of this view, that losses of ubstance of muscle which involve the destruction of these centres of nutrition re not replaced, like losses of cuticle, by new tissue of the same kind; the ower to form it not being inherent in the blood or in the neighbouring parts. Nevertheless it must be admitted that no intermediate stages of development can be traced in the fibres, even of those muscles of the adult which are in most constant use, and of which the nutrition is the most active, that are at all comparable to those which are met with in the muscular tissues of the embryo. —With regard, again, to the interstitial nutrition of Bones and Teeth, we have no certain knowledge. That some movement of nutritive fluid is continually taking place through them, is made apparent by the effects of madder in gradually tinging even the bones and teeth of the adult, though for such a change a much longer period is required in the adult than in the young animal; how far this movement, however, is subservient to any continual change of substance, still remains doubtful. If the supply of blood be withdrawn from a tooth or from a bone, or even from a part of the latter, the structures thus cut off from connection with the act of nutrition soon die, become detached from the living parts around, and are thrown out of the body. Of this we have a very good example in the annual exuviation of the antlers of the Deer, which is partly brought about by the choking up of the Haversian canals that give passage to blood-vessels, with concentric osseous deposit, and partly, as Lovén,* Kölliker,† Morison,‡ and others have shown, by the absorptive power of peculiar, multi-nucleated giant cells (the Myeloplasts or Osteoclasts of Robin, and Riesenzellen or giant cells of Virchow). Something of this kind seems to be continually taking place in ordinary Bone, upon a more limited scale; individual Haversian systems being removed by absorption, leaving spaces termed the Lacunæ of Howship, and being replaced by new formations of the same kind, probably during its whole life, without any change in external configuration. So far as can be gathered from observation, the process of interstitial decline and death usually takes place too rapidly for its stages to be perceptible, and is *immediately* followed, in the normal condition

of the system, by the removal of the effete particles; so that it is only when this removal is from any cause obstructed, as happens in the cases to be presently cited, that we see any indication of the *stages* through which the disintegrating tissues pass.

325. There is one remarkable form of degeneration, however, which is common to nearly all the tissues, and which seems to occur as a normal alteration in many of them at an advanced period of life; this consists in the conversion of their albuminous or gelatinous materials into fat, thus constituting what is known as *fatty degeneration*. That this change is not due to the removal of the normal components of the tissues, and the substitution of newly-deposited fatty matter in their place, but is (in most cases at least) the result of a real conversion of the one class of substances into the other, may now be considered as well ascertained.* And there are certain facts which indicate that this kind of degeneration is a part of the regular series of processes by which tissues that have served their purpose in the economy are prepared for being removed by absorption; one of the most remarkable being the observations of Virchow† and Kilian‡ with regard to the fatty degeneration of the muscular tissue of the uterus after parturition, and quite analogous phenomena are observed in muscles the motor nerves of which have been divided.§ So, as Sir J. Paget has pointed out, the fibrinous and corpuscular products of inflammation are often brought into a state fit for absorption, by passing through this intermediate stage; the fibrinous substance being observed to be dotted by granules which are recognized as oil-particles by their peculiar shining black-edged appearance, and at the same time losing its toughness and elasticity, and being no longer rendered transparent by acetic acid; whilst the lymph-cells present a similar increase of shining black-edged particles like minute oil-drops, which accumulate until they nearly fill the cell-cavity, their nuclei at the same time gradually fading and disappearing.‖ Thus, then, if the fat, which is one of the products of this retrograde metamorphosis, be absorbed as fast as it is formed, and the effete tissue be replaced by a new production (as seems to be the case with Muscles in a state of healthy activity), there is no appearance of degeneration, and the nutrition is kept up to its normal standard. So if, from the advance of age, or from the insufficient exercise of the muscles, their nutrition takes place less rapidly than their waste, whilst the products of their degeneration are still removed, simple atrophy is the result. If, on the other hand, the general conditions being similar, the fat produced in degeneration be not absorbed, but remain in the tissue, an obvious "fatty degeneration" is the result. This seems most likely to happen either when the fat is thus produced in such excessive amount, that the ordinary rate of its absorption (corresponding with that of its elimination by the combustive process) does not provide for its removal; which will occur when a large amount of tissue is undergoing degeneration at once, as in the case of the uterus after parturition: —or when the blood, being already highly charged with respiratory material,

* For an excellent account of the whole subject of Fatty Degeneration, see Dr. Handfield Jones's Articles in the "Brit. and For. Med.-Chir. Rev.," vol. xi. p. 327, and vol. xii. p. 30. In this country, a substantial description of the importance of the fatty degenerations was given, upwards of a quarter of a century ago, by Gulliver ("Trans. Med.-Chir. Soc.," 1843, vol. xxvi., and "Edinb. Med. and Surg. Journ.," July, 1843, p. 158), who thus early proved that these degenerations are a most frequent cause of the decay of the tissues, especially of aneurism of the arteries, and of that spontaneous bursting of their small branches which is the proximate cause of the most frequent form of apoplexy in the brain.

s indisposed to receive an additional amount of fat.* This distinct evidence of the operation of Alcohol habitually received into the blood in large quantities, affords an obvious indication that the habitual consumption of even a much smaller amount will tend to produce fatty degeneration at more remote periods and in a less aggravated degree; and the participation which this state has been shown to have in the production of a large proportion of the diseases of Old Age,—especially by the changes it induces in the texture of the heart and of the walls of the blood-vessels (which are particularly liable to it),—fully bears out this idea.

326. It may be stated as a general rule, that no absorption of the materials of tissues can take place without a previous degeneration such as this, or a more complete decomposition. There is no evidence that any *healthy* tissue is ever thus absorbed, or that any preternatural activity of the absorbent vessels can ever (as formerly supposed) be the *occasion* of a loss of substance; in fact, so long as the vital force is in active operation in a part, and its processes of growth and development are being normally carried on, such absorption may be considered to be impossible. On the other hand, if a part die *en masse*, it is not removed by absorption, but becomes isolated by the separation and recedence of the living parts, and is then cast out altogether, even from the interior of the body, as we see in the case of a necrosed bone; its condition being then essentially the same as that of the outer layers of the tegumentary organs, which are cut off, by their distance from a vascular surface, from all further nutrient change. The difference between these two modes of removal is well seen (as Sir J. Paget has remarked) in the case of the Teeth; for the fangs of the deciduous teeth undergo degeneration when the current of nutrition is diverted towards those which are to suceeed them, their materials being slowly decomposed, so as to become soluble, and being gradually removed by absorption, so that nothing is left at last but the crowns of the teeth; on the other hand, the permanent teeth, which are not to be succeeded by others, when no longer receiving their due nutrition, die, and are cast out entire.

327. Among the conditions of healthy Nutrition, a due supply of Nervous power is commonly enumerated; and it cannot be questioned that the want of such a supply is frequently the source of a perversion of the normal operations. This, however, by no means proves that the formative power is derived from the nervous system; and such an idea is at once negatived by a number of incontestable facts. Yet it may be freely admitted that the right direction and application of this power in nutrition may sometimes depend upon guidance and direction afforded by the Nervous centres, in the same manner as the Secreting process is capable of being thus affected; in fact, we can scarcely explain in any other mode that influence of mental states upon the nutrient operations which frequently leads to very important modifications of them. —The whole of this subject, however, will be more appropriately considered hereafter (CHAP. XVII.).†

* The quantity of fat in the blood of drunkards has been found in some cases to be as much as 11·7 parts in 1000 (Lecanu), the highest estimate of the quantity in health being 8·65 parts. Scharlau has found as much as 30 per cent. more carbon in the blood of a drunkard than in that of a healthy man.—See Dr. Huss's treatise on "Alcoholismus Chronicus," Rokitansky's "Handbuch der allgemeinen pathologischen Anatomie," Band iv., and "Brit. and For. Med.-Chir. Rev.," vol. xii. pp. 33, 34.

† In the treatment of this subject, the Author has made use of valuable illustrations contained in the first three of Sir J. Paget's "Lectures on Surgical Pathology;" the general doctrines, however, being such as he had himself expressed on many previous occasions.

3. *Varying Activity of the Nutritive Processes.—Reparative Operations.*

328. Without any change in the *character* of the Nutritive processes, there may be considerable variations in their *degree of activity;* and this, as regards either the entire organism or individual parts, though most commonly the latter. These variations may be so considerable as to constitute Disease; though there are some which take place as part of the regular series of Physiological phenomena. Thus, as we have seen, it is to the excess of formative activity that the increase of the organism in the earlier period of life is due, its 'waste' being at the same time extremely rapid; whilst it is to a corresponding reduction in the regenerative power, and not to positive excess of 'waste' or decay (this, indeed, taking place very slowly), that the gradual decline of the organism in advancing years is to be attributed. So also we find that local as well as general variations may take place, as a part of the regular series of vital phenomena; and this during the period of adult life, as well as in the earlier and later epochs. Thus all those differences in the proportional development of the several parts of the organism which mark the distinction between the adult and the child, even where (as in the case of a dwarf) there is no difference in stature, result from a decline in the formative capacity of those which are peculiarly adapted to the wants of the earlier stage (the Thymus Gland, for example), and from an increased activity of nutrition in those which are destined to the use of the adult, the Generative organs more particularly. And the intermittent activity of the sexual apparatus of the female affords a remarkable example of the same principle; this being marked, not merely in the enormous development of the uterus and mammary glands as a consequence of conception, but in the periodical change which takes place in the ovaries, whereby the ova are matured and thrown off at certain regular intervals. The decline in the formative power of these same organs, moreover, when as yet the organism in general shows but little indication of deterioration, is another characteristic example of the variation in Nutritive activity resulting from the inherent endowments of the part, and essentially irrespective of the condition of the blood, of the circulation, and of the organism as a whole; although, as formerly shown, the production and maintenance of other and apparently unconnected organs are *complementally* dependent upon the formative activity of the Generative apparatus.

329. The abnormal excess of Nutritive change which properly constitutes *Hypertrophy*, appears to depend upon a departure from one or other of the conditions under which, as already specified, the change normally takes place —namely, the right composition of the blood, a due supply of such blood, and a proper formative capacity in the blood itself.—Of the excess of nutrition resulting from the presence of an excess of the peculiar materials of certain tissues in the circulating fluid, examples have already been given. It is important to remark, however, that although hypertrophy may be thus induced in any of the tissues which constitute the instruments of *organic* life, yet there is no evidence that either the Nervous or the Muscular apparatus can be forced (so to speak) to an augmentation in bulk by the mere abundance of their nutritive materials.—With regard, in the next place, to the supply of blood, there can be no doubt that in general an increased flow of blood towards a part is consequent upon, rather than a cause of, an excess in its nutritive activity; but still there are cases in which its causative agency may be traced. Various examples of this have been supplied by the experiments and observa-

tions of John Hunter, the records of which are left in his Museum. Thus, if the spur of a cock be transplanted from the leg to the comb, which is a part far more vascular than that with which it was originally connected, it undergoes an extraordinary augmentation in size; having in one instance grown in a spiral form, until it was six inches long; and in another, curved forwards and downwards like a horn, so that its end needed to be often cut, to enable the bird to bring its beak to the ground in feeding. So, again, it was remarked by Hunter, and has been frequently observed since, that an increased growth of hair often takes place on surfaces to which there is an increased determination of blood as a consequence of inflammation in some neighbouring part, though not from the surface of the inflamed part itself. So it sometimes happens, that when an ulcer of the integuments of the leg has long existed in a young person, the subjacent bone may share in the increased afflux of blood, and may enlarge and elongate. And it seems not improbable that we are to attribute the increased thickness of the cuticle, on parts which are exposed to continual pressure or friction, to the augmented afflux of blood which is determined to the irritated surface.*

330. The greater number of cases of hypertrophy, however, must undoubtedly be referred to the preternatural formative capacity of the part itself, and this may either be congenital or acquired. Of this congenital excess, we have a remarkable example in the abnormal growth of an entire limb, or of fingers or toes,† which cannot with any probability be referred to an original excess in the supply of blood, the enlargement of the arteries leading towards such parts being almost certainly consequent upon their unusually rapid growth, just as in the case of the uterine and mammary arteries of the pregnant female. The most remarkable instances of the acquirement of increased formative activity are presented to us in that augmented growth of the nervous and muscular tissues, which is consequent upon the exercise of their functional powers. This may be considered as, to a certain extent, a normal adjustment of the supply to the demand; but there are some instances in which it takes place to such an extent as to become a positive disease. Thus it not unfrequently happens that if young persons who naturally show precocity of intellect are encouraged rather than checked in the use of the brain, the increased nutrition of the organ (which grows faster than its bony case) occasions pressure upon its vessels; it becomes indurated and inactive, and fatuity and coma may supervene. Now, although in such cases there may probably have been some congenital tendency to preternatural activity of the brain, which manifested itself in the precocity of intellect, yet there is no doubt that this may be augmented by the 'forcing system' of education; whilst, on the other hand, it may be controlled by a system of management adapted to the peculiar circumstances of the case. Excess of muscular development is peculiarly prone to show itself in the involuntary muscles; but this production is in almost every instance the result of the demand for increased muscular exertion which is consequent upon some obstruction to the usual function of the part. Thus an extraordinary hypertrophy of the muscular coat of the urinary bladder is often seen as a consequence of obstruction to the exit of the urine, through the presence of a stone in the bladder or of a stricture in the urethra. So,

* It is commonly said that local Hypertrophy may be induced by long-continued Congestion; but this is not true hypertrophy; for the bulk of the organ is not augmented by the increased production of its normal tissue, but by the addition of tissue of an inferior type of organization, as in Inflammation.

† A case of hypertrophy of an entire limb was described by Dr. John Reid in the "Edinb. Monthly Journ.," 1843, p. 198; and several cases of hypertrophy of the fingers were described by Mr. Curling in the "Med.-Chir. Trans.," vol. xxviii.

again, hypertrophy of the muscular coat of the gall-bladder may take place as a consequence of obstruction of its duct by a gall-stone. Hypertrophy of the muscular coat of any part of the alimentary canal may be induced by the existence of stricture lower down; and even hypertrophy of the heart is generally, if not always, attributable to obstruction to the exit of the blood which it propels, resulting either from stagnation of the pulmonary circulation by the deficient aëration consequent upon disease of the lungs (in which case the hypertrophy is limited to the right side of the heart), or from thickening or induration of the semilunar valves, or from narrowing of the orifices of the aorta and pulmonary artery. It is curious, moreover, to observe, that hypertrophy of muscles frequently becomes a source of increased nutrition of the bones to which they are attached; this being manifested, not merely in the augmented bulk of the bones of limbs that are specially exercised, but also in the increased prominence in the ridges and processes to which the muscles are attached. This adaptiveness on the part of the formative activity of the osseous tissue is curiously manifested also in the relation of the skull to the brain; for if the bulk of the brain be not too rapidly augmented, the skull will enlarge accordingly, and this (in some instances) not merely by the extension of its normal bones, but by the intercalation of new osseous elements, the 'ossa wormiana;' whilst, on the other hand, if there be a diminution in the bulk of the brain, the cranium may adapt itself to this also, by a thickening on its internal surface (or concentric hypertrophy),—this change, rather than a diminution in the entire substance of the skull, being more liable to take place in cases in which the cranial sutures have already closed, and the nutrition of the bone has become inactive.

331. The state of *Atrophy* is in all respects the very opposite of that of Hypertrophy; consisting in such a reduction in the rate of formative activity of the parts, as compared with that of their 'waste,' that their nutrition is no longer maintained at its previous standard; so that they are gradually reduced in bulk, or degenerate into some inferior histological type, or (which is more common) undergo both diminution and deterioration at the same time. It is important to bear in mind that Atrophy may take place, either locally or generally, from an unusually rapid disintegration of the tissues, uncompensated by a corresponding increase in the rate of their nutrition: of such local atrophy, we have a characteristic example in the rapid reduction of the bulk of the uterus after parturition, and of the mammary glands after the sudden cessation of lactation; of the general, we see an illustration in that rapid wasting of the system, which takes place in the irritable state that results from excessive and prolonged exertion of body or anxiety of mind, especially when accompanied with want of sleep, the increased disintegration being marked by the presence of an unusual amount of urea and of the alkaline phosphates in the urine. But in the ordinary forms of Atrophy, there is not merely a *relative* but an *absolute* reduction in the rate of the formative process, or a lowering of its standard of perfection; and here also we have to look for its causes, on the one hand, in the condition and supply of the blood, and on the other, in the formative capacity of the tissues themselves.—The Atrophy dependent upon an insufficient supply of nutritive materials may be either general or partial. General atrophy, or emaciation, is a necessary result of deficiency of food; but it may also proceed from an imperfect performance of the assimilating processes, whereby the nutritive materials do not receive their requisite elaboration, as in cases of disease of the mesenteric glands; or from an unusual energy of the metamorphic processes, whereby the azotized constituents of the food are decomposed into excrementitious products, without

undergoing assimilation at all, as seems to be the case in diabetes. Of the atrophy of a particular tissue, consequent upon the deficiency of its proper materials in the blood, we have an example in the reduction of the adipose tissue, when there is no surplus of fatty matter to serve for its nutrition, but, on the other hand, a withdrawal of the contents of the fat-cells into the circulating current, whilst the nutrition of the muscular and other azotized tissues may proceed with its usual vigour.—Instances of complete local atrophy, or gangrene, resulting from deficiency in the supply of blood to a part, are by no means unfrequent; but it is less common to meet with a prolonged diminution in the rate of nutrition from such a cause, since a partial obstruction to the circulation is usually removed after a short time by the enlargement of the collateral vessels. Yet there are peculiar circumstances under which this does not take place; thus Mr. Curling has shown that atrophy may occur in that portion of a fractured bone which is cut off from the direct supply of blood through the great nutrient artery; the circulation being restored by anastomosis to such an extent as to prevent the death of the bone, but not so completely as to support vigorous nutrition.*

332. The most frequent cause of Atrophy lies, however, in the deficiency of formative power in the tissues themselves, arising from the decline of that capacity which they inherit from the germ. This decline, as already shown, takes place in the body at large, as a part of the regular order of things, with the advance of years, and also normally occurs in particular organs at earlier periods of life; but it sometimes takes place prematurely, either in the body at large, or in particular organs, so that they undergo a wasting or degeneration without any ostensible cause. Thus it is not at all uncommon for Articular Cartilages to be almost entirely destroyed through defect of nutrition, without any pain or other symptoms to call attention to the change in progress;† and many similar cases might be cited. There is reason to believe that 'fatty degeneration,' the form under which degeneration most commonly presents itself, is in reality far more frequent than simple wasting; but it attracts less notice, because the bulk of the tissue is little or not at all diminished; and it is only when their function becomes impaired that attention is seriously drawn to the change. This form of Atrophy can seldom be attributed to antecedent diminution in functional activity; for it is most common in organs upon which there is the most constant demand for the energetic performance of their respective duties, as, for instance, in the heart, the kidneys, and the liver. But the formative activity of Muscles and Nerves is so closely dependent, as already several times pointed out, upon the active exercise of their functional powers, that atrophy is certain to supervene if this be interrupted; and this atrophy may or may not present itself under the form of fatty degeneration; a shrinkage of the parts, concurrently with the production of an increased amount of fat in them, being perhaps the mode in which it most frequently takes place. Atrophy of one part, moreover, may be dependent upon atrophy or imperfect functional activity of another, if the two be so related in their normal functions, that a decline of one involves a corresponding decline in the other. Thus, if a motor nerve be paralysed, the muscles which it habitually calls into action will be atrophied; and this will equally happen, whether the want of motive power depend upon a deficient production of it in the nervous centres, or upon an interruption to its conduction through the trunks. On the other hand, if the muscles of a part undergo degeneration from want of use (as in disease of the hip-joint), the

* "Medico-Chirurgical Transactions," vol. xx.

† See Redfern, "On Abnormal Nutrition in Articular Cartilages," p. 65.

nerves which supply them also suffer. The same is the case in regard to the nerves and organs of sense; for atrophy of the eye will occasion atrophy of the optic nerve, and destruction of the optic ganglia will induce atrophy of the eyes and optic nerves. Even the bones of a limb will suffer, in cases of atrophy of the muscles consequent upon disuse; for in an experiment made by Dr. J. Reid, to determine the effect of artificial exercise in maintaining the nutrition of muscles whose nerves had been divided, the bones of the quiescent limb only weighed 81 grains, whilst those of the exercised limb weighed 89 grains.*—It is an important fact, which was first pointed out by Sir J. Paget,† that when fatty degeneration is commencing in any tissue, which is characterized by the persistence of its nuclei, it is in the nuclei that the first alterations are seen; for they become pale and indistinct, and may even disappear altogether, almost before any other change is discernible in the contents of the cells or tubes to which they appertain; but in atrophy from mere decrease, this disappearance of the nuclei does not occur.

333. *Reparative Process.*—The nutritive operations take place with extraordinary energy and rapidity in the process of *Reparation;* by which losses of substance occasioned by injury or disease are made good. In its most perfect form, this process is exactly analogous to that of the *first development* of the corresponding parts; and its results are as complete in the one case as in the other. In fact, among the lowest tribes of Animals, we find these two conditions blended, as it were, together; for the process of reparation may be carried in them to such an extent, as to reproduce the whole organism from a very small portion of it. In the Hydra, or Fresh-water Polype, there would seem to be scarcely any limit to its power; for, even if the body of the animal be minced into small fragments, every one of these can produce a new and perfect being. In this manner, no less than forty have been artificially generated from a single individual.—In ascending the Animal scale, we find this reparative power less conspicuous, because limited in its exercise to particular tissues and to comparatively insignificant parts of the body;‡ and in Man, as in other warm-blooded Vertebrata, the regenerative power is for the most part restricted in its exercise, as Sir J. Paget has pointed out,§ to three classes of parts;—namely, (1.) "Those which are formed entirely by nutritive repetition, like the blood and epithelia (their germs being continually generated *de novo* in the ordinary condition of the body); (2.) Those which are of lowest organization, and (what seems of more importance) of lowest chemical character, as the connective tissues and the bones; (3.) Those which are inserted in other tissues, not as essential to their structure, but as accessories, as connecting or incorporating them with the other structures of vegetative or animal life, such as nerve-fibres or blood-vessels. With these exceptions, injuries or losses are capable of no more than repair in its limited sense—*i.e.*, in the place of what is lost, some lowly-organized tissue is formed, which fills up the breach, and suffices for the maintenance of a less perfect life."—Yet, even thus restricted, the operations of this power are frequently most remarkable; and are in no instance, perhaps, more strikingly displayed, than in the re-formation and re-modelling of an entire Bone, when the original one has been destroyed by disease. That this power is intimately related to that by which the organism is normally built up and maintained is evident, not merely from the peculiar mode in which it is exercised—its tendency being always to reproduce each part in the form and structure characteristic of it at the particular period of

* "Physiological, Anatomical, and Pathological Researches," p. 10.

‡ See "Princ. of Comp. Phys.," chap. xi. sect. 3. § Op. cit., p. 164.

life, and not according to its embryonic type—but also from the fact that it is more effectual in the state of growth than in the adult condition, and that it can do far more in the embryonic state, when development as well as growth is taking place, than after the developmental process has ceased. In fact, as Sir J. Paget has remarked (loc. cit.), its amount at different periods of existence, as in different classes of animals, seems to bear an inverse ratio to the degree of development which has already taken place. Thus it is well known to every practitioner, how much more readily and perfectly the lesions resulting from accident or disease are repaired in childhood and youth, than they are after the attainment of the adult state. And there is evidence that during embryonic life, the regeneration of lost parts may take place in a degree to which we have scarcely any parallel after birth; for Professor Simpson* has brought together numerous cases in which, after "spontaneous amputation" of the limbs of a fœtus, occurring at an early period of gestation, there has obviously been an imperfect attempt at the re-formation of the amputated part from the stump; and it seems probable, from the history of normal development, that in the cases in which perfect hands and feet have been present without the corresponding limbs, these hands and feet have been secondary productions from the stumps of amputated limbs, since any original defect of development would have affected the hands and feet rather than the arms and legs. There are occasional examples, moreover, in which this regenerative power has been prolonged to an unusually late period; thus an instance is recorded, on authority that can scarcely be doubted, of the twice repeated reproduction of a supernumerary thumb, after it had been twice completely removed;† and the Author has been assured by a very intelligent surgeon, that he was cognizant of a case in which the whole of one ramus of the lower jaw having been lost by disease in a young girl, the jaw had been completely regenerated, and teeth were developed and occupied their normal situations in it.‡

334. The regeneration of epithelium when the injury has been so slight as only to effect its abrasion has chiefly been studied in the case of the corneal epithelium,§ and appears to be effected chiefly by the adjoining cells thrusting out processes towards the wound and gradually bridging it over and covering it; but some new cells may also arise from the multiplication and development of the nuclei in the subjacent tissue, and there give rise to the formation of islands (Küss). The importance of the artificial aid that may be given to the efforts of nature in this direction are sufficiently shown in the remarkable results obtained by Reverdin in his method of treating ulcers by the transplantation of skin.‖ The reparation of somewhat deeper wounds, in which there has been so great a loss of substance that neither immediate union nor adhesion by a thin layer of coagulable lymph can take place, is accomplished by the gradual development of new tissue from the 'nucleated blastema' with which

* These cases were brought by Professor Simpson before the Physiological Section of the British Association, at its Meeting in Edinburgh, Aug. 1850. The Author, having had the opportunity of examining two living examples, as well as Professor Simpson's preparations, is perfectly satisfied as to the fact.

† See Mr. White's Treatise on the "Regeneration of Animal and Vegetable Substances" (1785), p. 16. A case was under Dr. Carpenter's observation, where the reproduction of a supernumerary digit, after removal, occurred *once*, and a second operation was postponed till the child had ceased to grow.—Ed.

the cavity is first filled. But this may take place in different modes, according to the degree in which it is disturbed by the Inflammatory process; and it should be the great object of the Surgeon to procure the most favourable method of its performance. It has been shown by Sir J. Paget* that the mode in which the process of filling up is accomplished differs essentially according as the wound is subcutaneous or is exposed to air. In the former case, the nucleated blastema is gradually developed into fibrous tissues without any loss, and usually with freedom from local inflammation (beyond what may have been requisite for the production of the plastic fluid), as well as from constitutional irritation. In the latter case, the nucleated blastema is developed into cells; and those on its exposed surface are unable, either from degeneration or from imperfect development, to pass on to any higher form of organization, but take on the characters of pus-cells, and are only fit to be cast off.† Hence there is a continual loss of plastic material, the amount of which in the case of an extensive suppurating sore, forms a most serious drain upon the system; whilst at the same time the local inflammation gives rise to more or less of constitutional disturbance, and the formation of new tissue is by no means so perfect as in the preceding case. In cold-blooded animals, however, the contact of air does not produce this disturbance; and we see wounds with extensive loss of substance gradually filled up in them by the development of new tissue, without any suppuration or other waste of material, very much as in the subcutaneous wounds of warm-blooded animals.

335. The most effectual means of promoting this kind of Reparative process, and of preventing the interference of Inflammation, vary according to the nature of the injury. The exclusion of air which almost invariably contains the germs of low organisms from the surface, and the regulation of the temperature, appear the two points of chief importance. The value of the former is well shown by the favourable results obtained by the plan suggested by Professor Lister,‡ of dressing wounds in an atmosphere saturated with carbolic acid spray and of the free application of carbolic acid to wounds, fistulous passages, &c., and by covering them with a paste formed of whiting, boiled linseed-oil, and carbolic acid.

CHAPTER XI.

OF SECRETION AND EXCRETION.

1. *Of Secretion in General.*

336. The literal meaning of the term Secretion is *separation;* and this is nearly its true acceptation in Physiology. But the ordinary processes of Nutrition involve a separation of certain of the components of the Blood, which are withdrawn from it by the appropriating power of the solid textures; and every such removal may be considered in the light of an act of *excretion*, so far

* Op. cit.

† The organizable material or lymph containing pus-corpuscles thus thrown out, constitutes a very favourable bed for the development and multiplication of the various spores which the researches of Tyndall ("Nature," vol. i. 1869–70, p. 339, and vol. iv. p. 124), as well as those of Dr. Cunningham and Lewis (Reports, Sanitary Board of Calcutta), have shown to be constantly floating in the air. At the temperature of the body, Bacteria, Vibriones, and other organic forms soon make their appearance in incalculable numbers, and accompany, if they do not produce, the putrefaction which takes place in the fluid. Burdon Sanderson, 'Lectures on Comparative Pathology,' "Brit. Med. Journal," 1877–78.

‡ "Lancet," 1867, pp. 326, 357, &c.

as the blood and the rest of the organism are concerned. Moreover, the separation of certain matters from the blood in a fluid state, either for the purpose of being cast forth from the body, or of being employed for some special purpose within it, which constitutes what is ordinarily known as Secretion, is effected by an instrumentality of the same nature with that whose operation constitutes an essential part of the nutritive process—namely, the production and subsequent agency of cells. Hence there is no other fundamental difference between the two processes, than such as arises out of the diverse *destinations* of the separated matters, and from the anatomical arrangements which respectively minister to these. For the products of the Secreting action are all poured forth, either upon the external surface of the body, or upon the lining of some of the cavities which communicate with it; and the cells by which they are separated from the blood usually stand in the relation of epithelium-cells to those prolongations of the skin or of mucous membranes, that form the follicles or extended tubuli of which the Glandular organs are for the most part composed. The act of Secretion appears to consist, in some cases, in the successive production and exuviation of the cells which minister to it, these cells giving up, by rupture or deliquescence, the substances which they have eliminated from the blood; such, for example, appears to be the mode of separation of the Sebaceous secretion of the skin, of the secretion of Milk, and perhaps also of the Biliary secretion. On the other hand, there can be little question that those more liquid secretions, in which there is either very little solid matter (as is the case with the Cutaneous transpiration and the Lachrymal fluid), or in which the solids, though in larger amount, are in a state of such perfect solution as to be capable of easy transudation (as is the case with the Urine), are not formed in this mode; since neither are exuviated cells normally found in the secreted fluids, nor do the epithelial cells lining the glandular tubes or follicles present indications of being in a state of continual change. The observations of Heidenhain and Langley are very instructive in this respect, for they show that in the case of the salivary glands, the cells lining the acini, when exhausted by secretion, are small, dark, and full of protoplasm, whilst after prolonged rest they are much larger and brighter, are no longer capable of being stained with carmine, and the protoplasm occupies a portion of the cell, where it appears in the form of the demilune of Giannuzzi. In this and similar cases, it seems fair to conclude that the *selective* powers of the cells are due to the protoplasm they contain; which during the period of rest is employed in elaborating from the surrounding blood or lymph the special secretion of the gland, and which under the influence of the nervous system swells up and causes the discharge of the contents of the cell, either by rupture, or, as seems more probable, by transudation.* However this may be,

* Giannuzzi, "Ber. d. Kön. Sächs. Gesell. d. Wiss. Sitz.," Nov. 27, 1865, suggested that in the case of the salivary secretion there is first an increased filtration of water from the blood into the lymph spaces, and secondly, a filtration of the water into the gland spaces. The former he thought was a mechanical result of the increase of the blood pressure in the capillaries when the chorda tympani was stimulated, whilst the latter was attributable to increased activity of the gland cells, consequent on stimulation of the true secretory nerves. But Heidenhain (Pflüger's "Archiv," Band xvii. 1878, p. 53) points out that stimulation of the chorda and of the nerve of Jacobson in atropinized rabbits, ought to cause œdema of the salivary glands, since this drug arrests secretion, whilst it does not interfere with the increased activity of the circulation, nor lead to any remarkable augmentation in the discharge of lymph through which channel any surplus fluid transuded through the walls of the distended vessels might be expected to escape. Hering ("Sitz. d. Wiener Akad.," Band lxvi.; Abt, vol. iii. 1872, p. 83) believed that in the case of the salivary glands, a colloidal substance like mucin, with high powers of imbibition, was produced in the gland

each group of cells is adapted to separate a product of some particular kind, which constitutes its special *pabulum;* and the rate of its production seems to depend, *cæteris paribus*, upon the amount of that pabulum supplied by the circulating fluid. The substances at the expense of which the secreting cells grow, however, may not be precisely those which are subsequently cast forth; for it is very probable that some of them at least undergo a certain degree of chemical transformation by the agency of these cells; the characteristic materials of the several secretions not being always found to pre-exist *as such* in the blood.

337. A distinction may be drawn as regards this point, between those *Excretions*, the retention of whose materials in the Blood would be positively injurious, and those *Secretions*, which are destined for particular purposes within the system, and the suspension of which has no immediate influence on any other functions than those for which they are respectively destined. The solid matter dissolved in the fluids of the latter class is little else than a portion of the *nutritive* constituents of the Blood; either so little altered as still to retain its nutritive character, as is the case with the casein of Milk, and with the albuminous constituent of the serous fluid of areolar tissue and of serous and synovial membranes; or in a state of incipient retrograde metamorphosis, as seems to be the case with the peculiar "ferments" of the salivary, gastric, pancreatic, and intestinal secretions. On the other hand, the characteristic ingredients of the Excretions are very different in character from the normal elements of the blood. They are all of them completely unorganizable; and they possess, for the most part, a simple atomic constitution. Some of them also have a tendency to assume a crystalline form; which, as Dr. Prout justly remarked, indicates their unfitness to enter into the composition of organized tissues. With regard to some of the chief of these, there is sufficient evidence of their existence, in small quantity, in the circulating Blood; but it is also clear that they exist there as products of decomposition, and that they are destined to be separated from it as speedily as possible. If their separation be prevented, they accumulate and communicate to the circulating fluid a positively deleterious character. Of this, we have already seen a striking example in the case of Asphyxia; and the history of the other two principal Excretions, the Bile and Urine, will furnish evidence to the same effect.—As a general fact, then, it may be affirmed, that the materials of the proper Excretions pre-exist in the Blood, in a state nearly resembling that in which they are thrown off by the secreting organs; and that, as their presence there is the result of the destructive changes that have taken place in the system, they cannot be retained in it without injury; but that the materials of those Secretions which are destined to perform some particular function within the economy, are derived from the nutritive substances which are appropriated to its general purposes.

338. Notwithstanding that, under ordinary circumstances, the several parts of the Excretory apparatus are limited, each to its own special function, we find that there are certain *complementary* relations between them, which makes the action of one vicarious to a certain extent with that of another. Such a relation seems to exist, for instance, between the Lungs on one side, and the Liver and Intestinal glands on the other: for, the more active the respiration, the less bile is secreted; whilst, if the respiration be lowered in amount

cells, and that this seized the water, and, dissolving in it, formed the secretion, which was discharged under comparatively high pressure; but Heidenhain again objects, that the pressure under which the saliva is secreted by the different glands bears no relation to the amount of mucin the cells contain. See Langley, "Journal of Physiology," vol. ii. 1879, p. 261; and Langley and Sewall, ibid. p. 281.

by inactivity of body and a high external temperature, a larger proportion of unoxidised or imperfectly oxidized excrementitious matters accumulates in the blood, giving rise to that augmented production both of the biliary and of the fæcal excretions, which constitutes diarrhœa.* And thus, on the other hand, when the liver is not adequately effecting the depuration of the blood from the constituents of bile, an augmentation of the respiration by active exercise in a low temperature gives most effectual relief.—Still more obviously vicarious, however, are the Kidneys and the Skin; for here we find that not only do the kidneys allow the transudation of whatever superfluous water may remain in the circulating current, after a sufficient amount has been exhaled from the skin to keep down the temperature of the body to its normal standard, but the skin actually assists in the elimination of one of those products of the metamorphosis of the azotised tissues, the removal of which has been until recently considered as the special function of the kidney. Consequently, whenever the due action of the skin as an excreting organ is interfered with, it is the kidney especially that will be called on to take its place; whilst, on the other hand, if it be thought desirable to relieve the kidney, this may be most effectually done by stimulating the skin to increased excretory activity. This vicariousness of function among the Excretory organs presents itself far more remarkably, however, in certain states of disease; in which a complete "metastasis of secretion" may exhibit itself. The capability of one organ thus to take upon itself the special action of another appears to be related to the "community of function" existing in the secretory surface among those lower animals which manifest none of the "specialization," or setting apart for particular offices, that we see in the higher; for it seems to be a general law in Physiology, that, even where the different functions are most highly specialized, the general structure retains, more or less, that primitive community of action which characterized it in the lowest grade of development.†

339. It is in regard to the *Urinary* excretion that the evidence on this point is most complete; for it seems to be established by a great mass of observations, that urine, or a fluid presenting its essential characters, may pass off by the mucous membrane of the intestinal canal, by the salivary, lachrymal, and mammary glands, by the testes, by the ears, nose and navel, by parts of the ordinary cutaneous surface, and even by serous membranes, such as the arachnoid tunic lining the ventricles of the brain, the pleura, and the peritoneum. A considerable number of such cases was collected by Haller;‡ many more were brought together by Nysten;§ and more recently Burdach‖ has furnished a full summary of the most important phenomena of the kind; and Dr. Laycock¶ has compiled a valuable collection of cases of urinary metastasis occurring as complications of hysteria. The following table of cases, referred to by the last of these authors, will give some idea of the relative frequency of the different forms of this curious affection:—

Vomit.	Stool.	Ears.	Eyes.	Saliva.	Nose.	Mammæ.	Navel.	Skin.	Total.
34	20	4	4	5	3	4	34	17	125

* Such is probably the occasion of the 'bilious attacks' and 'autumnal cholera' so prevalent at the close of the summer; the subjects of these being most commonly persons who have not reduced their consumption of food during the warm season, in accordance with the diminished demand for the production of heat within the body.

† See "Princ. of Comp. Phys.," §§ 110, 428. ‡ "Elementa Physiologiæ," tom. ii. p. 370.

§ "Recherches de la Physiologie et de Chimie pathologiques," p. 265.

‖ "Traité de Physiologie" (Jourdan's translation), vol. viii. p. 248, *et seq.*

¶ "Edinb. Med. and Surg. Journ.," 1838; and "Nervous Diseases of Women," p. 233.

It is to be borne in mind, however, that cases of hysterical ischuria are frequently complicated with that strange moral perversion which leads to the most persevering and ingenious attempts at deceit; and there can be little doubt that a good many of the instances on record, especially of urinous vomiting, are by no means veritable examples of metastasis.—The proofs of the fact we are seeking to establish are, therefore, much more satisfactory when drawn from experiments upon animals, or from pathological observations, about which, from their very nature, there can be no mistake. Thus Mayer* found that when the two kidneys were extirpated in the guinea-pig, the cavities of the peritoneum and the pleura, the ventricles of the brain, the stomach, and the intestinal canal, contained a brownish liquid having the odour of urine; that the tears exhaled the same odour; that the gall-bladder contained a brownish liquid not resembling bile; and that the testes, the epididymis, the vasa deferentia, and the vesiculæ seminales, were gorged with a liquid perfectly similar to urine. Chirac and Helvetius are quoted by Haller as having tied the renal arteries in dogs, and having then remarked that a urinous fluid was passed off from the stomach by vomiting. A considerable number of cases of the discharge of urine by exceptional means have been collected by Burdach.† In all the older statements of this kind, there is a deficiency of evidence that the fluids were really urinous, urea not having been obtained from them by chemical analysis, and the smell having been chiefly relied on. The urinous odour, however, when distinct, is probably nearly as good an indication of the presence of the most characteristic constituent of human urine, as is the appearance of the urea in its separated form. The passage of a urinous fluid from the skin has been frequently observed in cases in which the renal secretion was scanty; and the critical sweats by which attacks of gout sometimes terminate, contain urates and phosphates in such abundance as to form a powdery deposit on the surface.

340. The metastasis of the *Biliary* secretion is familiar to every practitioner, as being the change on which *jaundice* is dependent. It is not, however, in every case of yellowish-brown discoloration of the tissues, that we are to impute such discoloration to the presence of biliary matter; and we can only safely do so when we have at the same time evidence of concurrent obstruction of the biliary apparatus. The urinary apparatus then affords the principal channel through which the biliary matter is eliminated;‡ the urine becomes tinged with the colouring principle of bile, being sometimes of a yellowish or orange hue, and sometimes of a brown colour with a considerable sediment; and the presence of the most characteristic constituents of the bile has been determined in the urine. The same result presents itself when the biliary duct has been artificially obstructed by ligature. Other secretions have been found tinged with the colouring matter of bile; thus the pancreatic fluid has been seen of a yellow colour in jaundice; and the milk has presented not merely the hue, but the characteristic bitterness, of the biliary secretion. The cutaneous transpiration is not unfrequently so much impregnated with biliary matter, as to communicate its tinge to the linen covering the skin; and even the sputa of patients affected with bilious fevers have been observed to be similarly coloured, and have been found to contain biliary matter. The secretions of serous membranes, also, have been frequently seen to present the characteristic hue of bile; and biliary matter has been detected, by analysis, in the fluid of the pleural and peritoneal cavities. Biliary matter, however,

* "Zeitschrift für Physiologie," Band ii. p. 270. † Ibid. Band ii. pp. 253, 254.
‡ See J. W. Legg in "St. Barthol. Hospital Reports," vol. ix. p. 161.

when unduly present in the circulating current, is not removed from it by the secreting organs alone; for it seems to be withdrawn also in the ordinary operations of nutrition, entering into combination with the solid tissues. Thus, in persons affected with jaundice, we find the skin, the mucous and serous membranes, the lymphatic glands, the brain, the fibrous tissues, the cartilages, the bones and teeth, and even the hair, penetrated with the colouring matter of the bile, which they must have withdrawn from the blood, and which seems to have a particular affinity for the gelatinous tissues. It is impossible at present to say, however, to what extent the more characteristic ingredients of the bile are thus withdrawn from the blood; for the presence of its *colouring matter* cannot by any means be taken as an indication that its peculiar *resinoid acids* are also incorporated with the normal components of the tissues.

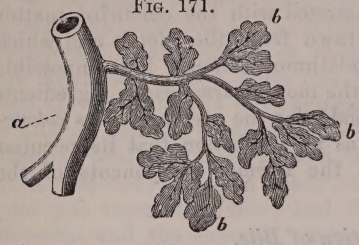
2. *The Liver.—Secretion of Bile.*

341. The Liver is only certainly known to be present in Vertebrate animals, for though in many Invertebrata large glands exist which pour the products of their secretion into the intestines, and may probably, especially when of a yellow colour, resemble bile in their action on the food, they have not as yet been shown to present the characteristic structure of the liver, nor to contain either true biliary colouring matter, nor, which is of much greater importance, the biliary acids; whilst other glands discharge their contents into the intestines, to which the function of secreting a biliary fluid might with equal reason be assigned. Even in the Amphioxus, the lowest of the Vertebrate series, no liver is present. In all other Vertebrated animals the Liver seems to be constructed on one and the same plan. Its component cells, which have not been proved to possess a definite cell-wall, are contained in distinct cæcal follicles, or elongated tubuli, branching off from the excretory ducts; but in ascending through the Vertebrated series, it presents a more and more solid parenchymatous texture. This character is very obvious in the liver of Man, which is peculiarly firm and compact, and has less of connective tissue between its different parts than is found in that of many other Mammalia.—It is observable, moreover, in the Human liver, that certain portions are rudimentary, which are elsewhere fully developed. The liver in Mammalia, as in the lower vertebrates, is essentially a bilobed organ, but this character is usually more or less concealed by the various accessory fissures by which it is divided into many lobes; always, however, on the same general plan. The fissure in which the umbilical vein runs constitutes the primary division into right and left segments. In the most complex forms usually met with in the Quadrumana, Carnivora, Insectivora, Rodentia, Edentata, Marsupialia, &c., the left segment is further divided by the *left-lateral fissure* into a *left-lateral* and a *left-central lobe*. The right segment is similarly divided into a *right-central* and *right-lateral lobe*; and it has, moreover, two accessory lobes on its under surface, the Spigelian and the caudate. When the gall-bladder is present it is attached to the under surface of the right-central lobe. In most Ungulates, in Cetacea, in the highest Apes, and in Man, the lateral fissures are not present, and the liver appears of simpler form. In Man the simplicity is further increased by the caudate being hardly distinguishable from the right-lateral lobe and the Spigelian lobe being but little developed.*

* See W. H. Flower 'On the Organs of Digestion of Mammalia,' "Med. Times and Gazette," March 9th, 1872, *et seq.* The weight of the Liver is from 48–58 ozs. in the male, and from 40–50 ozs. in the female. Its sp. gr. is about 1·05. From the examination of a large number of bodies, Steffan ("Jahrbuch f. Kinderheilk.," N. F. Band v. p. 47) found

342. When the liver is closely examined with the naked eye, it is seen to be made-up of a great number of small granular bodies, about the size of millet-seeds, of an irregular form, and presenting a number of rounded projecting processes upon their surfaces. These are commonly termed *lobules*, although by some Anatomists they are spoken of as *acini*.* When divided longitudinally, they have a somewhat foliated appearance (Fig. 171), arising from the distribution of the Hepatic Vein, which spreads from the centre of each division. When transversely divided, the lobules are usually found to present somewhat of a pentagonal or hexagonal shape, the angles being slightly rounded, so as to form a series of passages or interlobular spaces: in these lie the branches of the Vena Portæ (as well as of the Hepatic Artery and Duct), from which are derived the plexuses that are contained within the lobules. The exterior of each lobule is covered by a process of the 'capsule of Glisson,' which is very dense in the Pig and other animals but is so thin as to be almost indistinguishable in the Human Liver; the interspaces between the vessels are filled by the ultimate terminations of the Hepatic biliary ducts, which contain large secreting cells.† The structure of each lobule, then, gives us the essential characters of the whole gland.

Fig. 171.



Connection of the *Lobules of the Liver* with the Hepatic Vein:—*a*, trunk of the Vein; *b*, *b*, lobules depending from its branches, like leaves on a tree; the centre of each being occupied by a venous twig, the Intralobular Vein.

343. The supply of arterial blood, and therefore of loosely-combined oxygen to the liver, is remarkably small as compared with other organs. The diameter of the Hepatic Artery in man is only 5·6 millimetres (1-5th of an inch), whilst that of the Splenic Artery is from 6·2–6·8 mm., and that of the Renal Artery from 5·6 to 6·8 mm. Yet the relative weights of these three organs are—liver 1400–1900 grammes, spleen 120–250 grammes, and kidney 116–174 grammes. The *Hepatic Artery* sends branches to every part of the Liver, supplying the walls of the portal and hepatic veins, and of the hepatic ducts, as well as Glisson's capsule. The principal distribution of its branches, however, is to the lobules, which they reach, in the same manner as the portal vessels and biliary ducts, by spreading themselves through the interlobular spaces. There they ramify upon the interlobular ducts, and upon the capsular surface of the lobules, which they then penetrate; terminating for the most part in the portal venous plexus, though a very few small branches may be traced into the Hepatic plexus of capillaries. The whole of the blood, therefore, of the Hepatic Artery passes through the lobuli, and is subservient to the secretion of Bile. But if the liver be sparingly supplied with arterial, it receives a large amount of venous blood. The *Vena Portæ*, which is formed by the convergence of the veins that return the blood from the chylopoietic viscera, probably also receives the blood which is conveyed to the liver for the

that the ratio of the weight of the Liver to the body weight is greatest after birth, and that it diminishes during the first year, especially in boys. In childhood the body weight and the liver weight increase, but not in equal proportion, the former augmenting most rapidly.

* The *acini* of Malpighi are the minute bodies of various forms and yellowish colour, which are seen when any individual lobule is examined with the microscope; these are nothing else, however, than the irregular islets of parenchyma, left between the meshes of the plexus formed by the ultimate ramifications of the portal vein.

† See Prof. Beale's paper 'On the Ultimate Arrangement of the Biliary Ducts,' in "Phil. Trans.," 1856, and Todd and Bowman's "Physiolog. Anat.," p. 459, vol. ii., 1859.

purposes of nutrition by the Hepatic Artery. Its diameter is 15·79 mm. Like an artery, it gradually subdivides into smaller and yet smaller branches; and at last it forms a plexus of vessels, which lie in the inter-lobular spaces, and spread with the freest inosculation throughout the entire Liver. To these vessels, the name of *inter*-lobular Veins was given by Mr. Kiernan.* They ramify in the capsules of the lobules, covering with their ramifications the whole external surface of these; and then enter their substance. When they enter the lobules, they are termed *lobular* veins; and the plexus formed by their convergence from the circumference of each lobule towards its centre is designated as the *lobular venous plexus*. The ultimate ramifications terminate in those of the intra-lobular, which discharge themselves into the sub-lobular veins, and through them into the hepatic vein. It now only remains to describe the *Hepatic Veins*, the branches of which occupy the interior of the lobules, and are termed *intra*-lobular veins (Fig. 172, *a*, *a*, Fig. 173). On making a transverse section of a lobule, it is seen that the central vessel is formed by the convergence of numerous minute venules, which arise from the plexus upon the surface of the lobule. The intra-lobular veins terminate in the larger trunks, which pass along the bases of the lobules, discharging into them their venous blood; these are called by Mr. Kiernan *sub-lobular* veins. The main trunk of the Hepatic Vein terminates in the ascending Vena Cava. The pressure of the blood in the Hepatic Veins varies from + 3 or 4 mm. to − 7 mm. of Mercury, whilst it amounts to between + 7 and + 16 mm. in the Vena Portæ,† and the time occupied by the circulation of a given quantity of blood through it is probably not far short of that taken up by the major circulation, *i.e.*, from the crural vein to the crural artery.‡

344. The *Hepatic Duct* forms, by its subdivision and ramification, an inter-lobular plexus very like that of the portal vein; the branches ramifying upon the capsular surface of the lobules, and ultimately penetrating into the interior (Fig. 174). The trunk and larger branches of the biliary duct consist of an internal mucous membrane and an external fibrous sheath. The former is very vascular and is lined by tall columnar cells; the latter is believed by Hering to contain smooth muscular fibres, arranged longitudinally, and a few blood-vessels; Asp, however, believes the spindle-cells and striated appearance relied upon by Hering, Heidenhain, and others, as evidence of muscular fibres to be due to elongated nuclei and connective tissue fibres, as they swell up and disappear in weak solution of hydrochloric acid and alcohol. At the point where the inter-lobular ducts become continuous with the network within the lobules, their diameter is very small, not exceeding 1–4000th to 1–5000th of an inch; and here the

epithelium, which in the medium-sized ducts remains columnar, passing in the smaller ducts into the tessellated variety, suddenly becomes spheroidal, or assumes the form of the true secreting cell. The tubes, of the diameter of 1–80th of an inch and larger, present many little saccular dilatations of the coats, the openings of which, according to Dr. Beale, are regularly arranged in two rows or lines on opposite sides of the ducts; and besides these are numerous small, irregular, and anastomosing canals, which run obliquely in the coats of the ducts, and ultimately open into their cavities.

states he has repeated Lehmann's experiments, and is unable to confirm them. He thinks that there is no perceptible difference between Portal venous and Hepatic venous blood.

These tubes and cæca may be regarded as accessory gall-bladders, in which the bile, secreted and stored up, comes into intimate relation with a fine plexus of capillaries, and may perhaps undergo further elaboration. In regard to the mode of termination of the finest biliary ducts it appears from the observations of Hering and others,* that, when injected, the canals existing between the large secreting cells form a close plexus (Fig. 175,*a*), the meshes of which appear to enclose the hepatic cells, though in reality the lines of injection follow the spaces between the large secreting cells (Beale). In the Rabbit these canals run exclusively, and in Man and the Dog in by far the greatest number, not along the angles, but between the opposite surfaces (Fig. 176) of two adjacent cells, dividing their surfaces sometimes into two equal halves and at others unequally. The blood capillaries (Fig. 176, *c*), on the other hand, chiefly run in the angles formed by the junction of three or more cells. According to Hering, the biliary canals and passages do not possess any membrana propria, their walls being formed by the hepatic cells themselves, which succeed suddenly to the flattened polyhedric cells of the smaller biliary ducts, but MacGillavry and Chrzonsczsczewsky maintain that they have proper walls, the bile secreting cells lying (Fig. 175) to their outside, though this is perhaps illusory, the supposed vascular wall being only a thickening of the cell-wall. Both Weber and Asp, from injections with gamboge dissolved in spirit (Weber), and alkanet in turpentine (Asp), have observed that under moderate pressure the fluid injected will often penetrate directly from the smaller biliary ducts into the biliary cells, the so-called biliary capillaries then entirely disappearing, and the peripheric part of the lobules becoming deeply stained; on subsequently injecting Prussian blue, Asp found that it was retained in the passages it would under ordinary circumstances have run in, and did not enter the cells, precluding, in his opinion, the idea that there are any coarse openings between the biliary ducts and liver cells. The demonstration of the ultimate biliary canals by the injection of coloured fluids is extremely difficult in Man, on account of the coagulation of their contents soon after death. They have, however, been very distinctly seen as the result of disease in animals,† and may perhaps hereafter be in this way made apparent in the human subject.

polyhedric spheroidal form, channelled at their angles by the capillaries, and on their surfaces by the biliary canals, and are from 1–500th to 1–2000th of an inch in diameter. Each of them, generally, but not always (Asp), presents one or two distinct nuclei containing numerous granules; and the cavity of the cell is occupied by yellow amorphous biliary matter, usually having one or two large adipose globules, or five or six small ones, intermingled with it (Fig. 177, *a*, *b*). The biliary cells contain albuminous substances, which, after death, yield a globulin, an albumin coagulating in a weak neutral saline solution, at a temperature of 45° C. (113° F.), and another albuminous substance which dissolves very slowly in dilute solution of soda, and hence cannot be identical with alkali albuminate. Plosz, by freezing, mincing and pressing the liver, obtained a spontaneously coagulating fluid, as Kühne did from the muscles. Plosz also obtained nuclein from the liver substance, which was derived from the nuclei of the cells. In life the liver parenchyma is alkaline, but after commencing stiffening, it is neutral, and finally acid. The size and number of the oil globules vary considerably, according to the nature of the food, the amount of exercise recently taken, and other circumstances. If an animal be very fat or be well fed, especially with farinaceous or oleaginous substances, the proportion of adipose particles (Fig. 177, *c*) is much greater than in an animal moderately fed and taking much exercise. The size of the oil-globules varies from that of mere points, scarcely distinguishable from the granular contents of the cells except by their intense blackness, up to one-fourth of the diameter of the cell. A still greater accumulation of adipose particles in the biliary cells gives rise, as was first pointed out by Mr. Bowman,* to the peculiar condition termed "fatty liver." The finely granular matter is the portion from which the colour of the cell is derived; it seems to fill the space not occupied by the oil-globules; and it often obscures the nucleus, so that the latter cannot be distinguished until acetic acid is added, which makes the granular matter more transparent without affecting the nucleus.†—The Liver, therefore, belongs to the class of ramified tubular glands; and the materials of the biliary secretion formed from the blood by the cells lining the intralobular extremities of the ducts are discharged into the interior of these canals, either by exudation or by the deliquescence of the cells themselves. Teichmann‡ describes the lymphatics as running with the portal venous branches, and the biliary ducts as forming a plexus with large, irregular meshes on the outside of the lobuli, and he believes he has even injected minute branches passing up their centre with the Vena intralobularis of the Hepatic Veins.

* "Medical Gazette," Jan. 1842.

† Schiff ("Archiv f. Phys. Heilk.," 1857, p. 263, and "Untersuch. üb. die Zuckerbildung in der Leber," &c., Wurz. 1859) described two kinds of granules in the Liver cells besides the nucleus; one of these was dark-bordered and highly refractile, the other much smaller and pale. These last he thought were particles of Glycogen. Bock and Hoffman (Virchow's "Archiv," 1872, Band lvi. p. 202) deny this on the grounds of their chemical reaction and the want of relation between their numbers and the amount of Glycogen in the Liver, and believe that it exists in the form of a homogeneous mass. For an account of the albuminous compounds of the Liver, see Plosz, Pflüger's "Archiv," 1873, Band vii. p. 371. Schenk ("Centralblatt," 1869, p. 865) has described peculiar protoplasmic masses resembling amœbæ in possessing spontaneous movement, as being present in the embryonal Liver of mammals, and Pflüger ("Archiv f. ges. Physiol.," Band ii. p. 459) states that the liver cells possess processes like those of the salivary cells, and appears to think there is some communication between the biliary canaliculi and the interior of the cells; since, if the capillary ducts of the biliary canals are injected with cold Prussian blue injection, fine ducts may be seen to penetrate the protoplasm of the cells, which divide and surround the uncoloured nucleus. MacGillavry had previously noticed that on injection of the lymphatics with cold Prussian blue the *nuclei* of the colourless hepatic cells became deeply stained.

‡ "Saugader System," p. 94, Leipzig, 1861.

MacGillavry* describes the lymphatics of the liver of the rabbit as forming loose sheaths to the vessels, and his statements have been confirmed by Asp. Similar sheaths have been observed by Irminger and Frey around the blood-vessels of the liver of the dog. Wendt is of opinion, from physiological injections of Prussian blue, that is, the injection of colouring matter into the Veins of the living animal, the Venæ Portæ being tied, that in the guinea pig the finest roots of the lymphatic system are continuous with the commencement of the biliary ducts. A single layer of lymphatics exists on the peritoneal surface of the liver, lying in the subserous areolar tissue. The nerves of the Liver have been carefully examined by Dr. Robert Lee,† Hering,‡ and Pflüger.§ Dr. Lee has shown them to arise chiefly from the semilunar ganglion and sympathetic plexus surrounding the root of the hepatic artery, the minutest branches of which they accompany. Some fibres are derived from the left pneumogastric nerve. Pflüger believes he has been able to trace the nerves into connection with the hepatic cells, but Hering maintains that all demonstrable nerves lie on the outer side of the lobules.

346. The first and most obvious function performed by the Liver is the secretion of Bile. For this the arrangement of the cells and ducts appears to be primarily designed; and by their means a considerable quantity of material, rich in carbon and hydrogen, is, temporarily at least, eliminated from the blood, whilst at the same time a liquid is provided, the utility of which in promoting the absorption of food, and especially of oleaginous food, has been already sufficiently considered (§ 128). But the large size of this organ in comparison with the amount of secretion poured into the alimentary canal; its constant presence in almost all classes of animals, how various soever the nature of their food may be; its manifest activity in the fœtus before the ingestion of any food has taken place; the large supply of blood which it receives from different sources, as well as the peculiar relations which it holds to the blood returning from the placenta in the fœtus, and from the abdominal viscera in the adult—are all circumstances suggesting that other functions than the secretion of the Bile are here performed; and from the results of comparatively recent research it may now be considered as fairly established, that it exerts an assimilative or elaborating action on the freshly-absorbed materials of our food, and especially upon the albuminous and saccharine constituents, whereby they become more fitted for the nutrition of the body; and that in the course of these assimilative changes, the activity of which is indicated by the high temperature of the organ, and is perhaps a consequence of them, a material analogous to starch—glycogen—is formed, whose ultimate destination is still undetermined, but which there is some reason for believing in part, either directly or indirectly, combines with oxygen, and thus becomes subservient to the maintenance of animal heat, and in part is on the way to histological formation. The production of this substance is termed Glycogeny, and will be considered after the characters and mode of formation of the Bile

Bile is a viscid, neutral or feebly-alkaline, somewhat oily-looking liquid, of a greenish-yellow colour, and very bitter taste, followed by a sweetish after-taste. It is readily miscible with water, and in solution froths like one of soap. Its specific gravity in the human subject is about 1·018, the extremes being 1·0105 and 1·032. According to Kowalewsky† the pressure of the Bile in the ductus communis choledochus under ordinary circumstances in curarized cats, varies from 3·5 to 7·5 mm. of mercury (2–4 in. of water), rising if the duct be ligatured to from 12 to 20 mm. of mercury (6–11 in. of water). Heidenhain states that it is secreted under a pressure of a column of water, eight inches in height. The proportion of solid matter which it contains is usually from 9 to 17 per. cent., and nearly the whole of this consists of substances peculiar to Bile. 100 parts of human Bile purified and dried at 230° F. contain about 1·5 parts of sulphur. The gases of the Bile‡ are oxygen, carbonic acid, and nitrogen, but their proportion seems to vary within rather wide limits, being greatest if collected immediately after death. Thus the oxygen in the bile of the dog varies from 0 to 1·22 vol. per cent., carbonic acid capable of being removed by the air-pump from 0 to 19·5 vol., carbonic acid capable of being expelled by Phosphoric acid 0·6 to 62·5 vol., and Nitrogen from 0·4 to 9·13 vol. per cent. The constituents of the Bile are mucin, diastatic ferment, salts of biliary acids; the colouring matters, bilirubin and biliverdin, lecithin, cholesterin, urea, oleates, stearates and palmitates of the alkalies, as well as salts of certain volatile fatty acids; olein, palmitin, stearin, and various salts, as sodium chloride, and iron, magnesium and calcium phosphate. The biliary salts in man constitute about 6·5 per cent. of the bile, of which taurocholate of soda forms 1·5 parts, and glycocholate of soda 5 parts. Besides these salts substances insoluble in alcohol (chiefly mucin) constitute 3·5 parts, and soaps 1·5 per cent. The quantity of sulphur is about one-tenth per cent.,§ which is chiefly contained in the taurocholic acid, no less than 25 per cent. of that element existing in Taurin, so that the proportion

* "Phys. Chem.," 1875, p. 529. † Pflüger's "Archiv," Band viii. Heft xii.

‡ These have been examined by Pflüger, "Pflüger's Archiv," Band ii. 1869, p. 173; Bogoljubow, "Centralblatt f. d. Med. Wiss.," 1869, and Noel, "Etude général sur les gaz du Sang. Thése.," Paris, 1876.

§ See Trifanowski, Pflüger's "Archiv," Band ix 1874, p. 492, and Socoloff, idem., Band xii. 1875, p. 54.

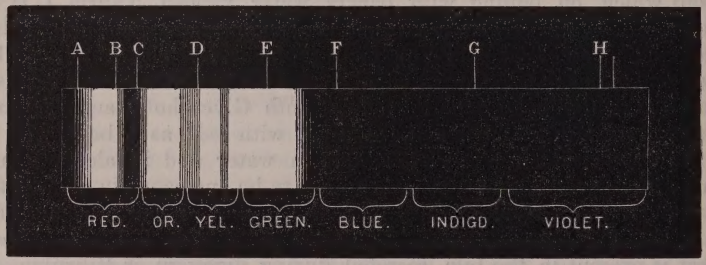
this acid bears to the glycocholic (which differs greatly in different animals) may be estimated by the amount of sulphur in the mixture of the two. The bile often contains copper. The *mucin* varies in quantity, and appears to be derived from the epithelial cells of the excretory ducts and gall-bladder, and not from the liver cells, since its quantity is lowest when the secretory activity of the organ is at its height. The *diastatic ferment* is small in quantity,* but has been found in the bile of the frog, pike, carp, goose, duck, chicken, sheep, ox, pig, rabbit, cat, and horse, and in Man. The most important constituents of the Bile are the salts of the biliary acids and the colouring matters. Gmelin found that on the addition of neutral acetate of lead to fresh ox gall, a resinous and crystalline acid was precipitated, to which he gave the name of cholic acid. Strecker determined the formula of cholic acid to be $C_{26}H_{43}NO_6$, and observed that when it was boiled with saturated baryta water, it takes up one eq. of water, and breaks up into Glycocol, $C_2H_5NO_2$, and Cholalic acid, $C_{24}H_{40}O_5$. Lehmann afterwards, to avoid confusion, termed the cholic acid of Gmelin Glycocholic acid, by which name it has since been recognised. Strecker further showed that ox gall contained another acid, which he termed choleinic acid, and which, on boiling with baryta water, yielded, Taurin, $C_2H_7NSO_3$, and cholalic acid, one eq. of water being at the same time taken up. Lehmann changed the name of Choleinic to Taurocholic acid. The acid of the bile of fish, serpents, and the sheep is chiefly, and of the dog almost exclusively, composed of Taurocholic acid. In man, both Glycocholic and Taurocholic acids are present in the bile, and are united with soda as a base, with which they form salts that are readily soluble in water and in alcohol, but are insoluble in ether. These two acids appear to be analogous in composition to Hippuric acid, and to be composed of Glycocoll or of Taurin combined with Cholalic acid.† The chief colouring matter of the bile, and almost the only one that is present in the bile secreted during digestion, is Bilirubin, which has a beautiful bluish-green colour, and is capable of being converted by oxidation into the second colouring matter which is chiefly present in the greenish bile secreted by cold-blooded animals, and by warm-blooded animals during the fasting state, and is named Biliverdin. Both are found in considerable quantity at the borders of the placenta in the dog, and probably in other animals, and bilirubin occurs as a pathological product in old extravasations of blood; Bilirubin is here sometimes seen in the form of small rhombohedral crystals, and constitutes the Hæmatoidin crystals of Virchow.

* Jacobson, "De Sacchari formatione," &c., Regimont, 1865; and Wittich, Pflüger's "Archiv," Band vi. p. 181, 1872.

† The precise chemical composition of cholalic acid is unknown, but is taken as $C_{24}H_{40}O_5$. It is not present in fresh bile nor in any tissue of the body. In the intestinal canal it is formed from the taurocholic acid, and is in part discharged with the fæces. It is easily soluble in alcohol, but dissolves with difficulty in ether, and not at all in water. From the ethereal solution it crystallizes in prisms, and from its solution in diluted alcohol in tetrahedra. When separated from the watery solution of one of its salts, it is precipitated in a tenacious resin-like state, which crystallizes readily on the addition of a little ether. It is not volatile. Baryta cholalate is soluble in 30 parts of cold, and in 23 parts of boiling water, which affords a means of distinguishing its salts from those of the fatty acids. All combinations of cholalic acid exhibit when in solution right-handed circumpolarization, in this respect differing from all other substances found in the body, with the exception of grape sugar and Glycogen. On being heated to 200° C. (392° F.), or on being boiled with strong hydrochloric acid, cholalic acid yields the anhydride, $C_{24}H_{36}O_3$, called also dyslysin. When boiled with dilute sulphuric or hydrochloric acid, an amorphous substance is formed, which has been named choloidinic acid, but which is only a mixture of cholalic acid and dyslysin. Heated to fusion with caustic alkali, dyslysin takes up water and again forms pure potash cholalate. The bile of the pig contains the glycocoll and taurin compounds of an acid allied to cholalic acid and named hyocholalic acid, $C_{25}H_{40}O_4$. The bile of the goose again contains the salts of another acid combined with taurin, named the chenocholalic acid, $C_{27}H_{44}O_4$.

Its composition is differently given as $C_{32}H_{36}N_4O_6$ (Städeler and Maly), and as $C_9H_9N_9O_2$ (Thudichum).* Various experiments tend to show that the biliary colouring matters are not formed exclusively in and by the Liver, but rather that they are in part preformed in the Blood, so quickly is their elimination from the body effected. It is remarkable that, notwithstanding the comparatively-minute proportion in which the cholesterin and colouring matter exists in ordinary bile, cholesterin should usually be the principal ingredient of the biliary concretions which are frequently found in the gall-bladder and bile-ducts; and that the bile-pigment with choloidinic acid and a calcareous base should also occasionally accumulate, so as to form solid masses which consist of little else. The fresh normal Bile of man, the cow, pig, and dog, exhibits no absorption bands, though these appear in the alcoholic extract when the bile has undergone change.† Dr. Dalton,‡ working with sheep's Bile, finds that the spectrum is very short, the light being totally absorbed at a considerable distance from the refrangible end, and that it terminates suddenly. It presents, as is shown in the accompanying diagram, three absorption-

Fig. 178.



Spectrum of green bile.

bands, one in the red at the situation of the line C, which appears to be due to the green rather than the red colouring matter of the bile.§ A second, much more faint and less constant in position, situated at the junction of the

* The nature of the colouring matters has not been very accurately determined—for Städeler (1863) isolated five distinct compounds: Bilifulvin, Biliverdin, Bilifuscin, Biliprasin, and Bilihumin; whilst Maly (1864, Bernard, 'Physiologie Générale,' "Revue Scientifique," 1873, p. 462) finds only one substance, Cholepyrrhin; and Dr. Thudichum (1872, "Clinical Physiology," 1872, p. 18), describes two, Cholophæin or Bilirubin, $C_9H_9NO_2$, and Bilifuscin, $C_9H_{11}NO_3$. The relationship of these colouring matters to the colouring matter of the Blood, first suggested by Virchow, ("Archiv f. Path. Anat.," Band i. 1848, p. 421) has been rendered probable by the discovery of Zenker ("Jahresbericht von der Gesellsch. f. Natur und Heilkunde in Dresden," 1858, p. 53) of crystals of Hæmatoidin in inspissated Bile, by the circumstance that both contain iron, and by the observation of Gübler ("Gaz. Méd. de Paris," 1859, p. 469) that Bilirubin and Hæmatin give the same play of colours with HNO_3, except that the green colour is most persistent in the former and the violet in the latter. R. Maly ("Centralblatt f. d. Med. Wiss.," 1871, p. 849, and "Annal. der Chemie u. Pharm." Band clxiii. p. 77, 1872) has pointed out that there is a close relation between Cholepyrrhin, or Bilirubin, and the colouring matter of the Urine obtained by Jaffe (Virchow's "Archiv," Band xlvii.), and named by him Urobilin, and with the colouring matter of the fæces obtained by Vanlair and Masius ("Centralblatt f. d. Med. Wiss.," 1871, p. 369). Feltz and Ritter (Robin's "Journal de l'Anatomie," 1875, p. 162), and Tarchanoff (Pflüger's "Archiv," 1874, Band ix. p. 329), have shown that if the colouring matters of the Bile or of the Blood are directly injected into the Blood, they are rapidly excreted in a more or less modified condition by the Urine.

† Foster, "Text Book of Physiology," 1878, p. 196.

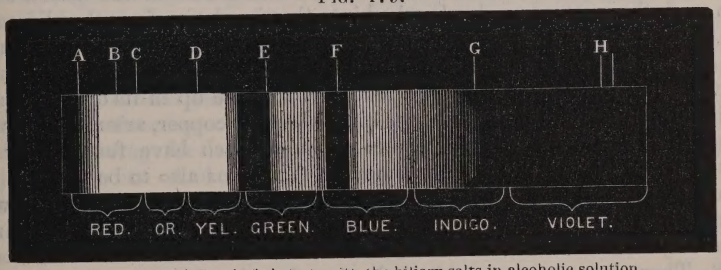
‡ "A Treatise on Human Physiology," 6th edit. 1876, p. 209.

§ On Vierordt's system of notation, in which the eight principal lines of the solar spectrum are taken as fixed points, A, B, C, D, E, F, G, and H, and the spaces between these considered as divided into 100 equal parts, the exact position of the band was in one case from B 20 C to C 10 D, and in another from B 13 C to C 18 D.

orange and yellow immediately to the left of the line D; and a third, which is very narrow, situated at about one-third the distance between D and E. The principal band at C corresponds very closely with the absorption-band of chlorophyll. As a rule, also, it presents a remarkable diminution in quality of the orange and red colours. Both Dalton and Schenk* obtained the spectrum (Fig. 179) from the purple fluid, resulting from the action of Pettenkofer's test on solutions of the taurocholate and glycocholate of Soda, exhibiting two wide and dark absorption-bands, one at E, extending from D 50 E, to E 25 F; the other at F, from E 60 F, to F 15 G, the spectrum terminating gradually about the line G. v. Wittich, in a case of biliary fistula in the human subject, found that the fresh bile contained a ferment capable of converting starch into sugar.† The index of refraction of bile for light was found by Valentin to be 1·3478; the specimen was not freed from mucus, and was taken from a subject several days after death.‡

347. We have now to inquire into the conditions under which the Secretion of Bile takes place; and one of the most important of these is the supply of

Fig. 179.



Spectrum of Pettenkofer's test, with the biliary salts in alcoholic solution.

Blood which the Liver receives. How far the blood supplied by the Hepatic Artery is the immediate source of the secretion has not been quite satisfactorily determined. Kottmeier§ and Küthe‖ found that no bile was secreted after ligature of this vessel, and they attribute the result to an alteration taking place in the nutrition of the cells destined to form the bile. Schiff, however, was unable to detect any diminution in a large dog upon which he had performed the same operation, and Röhrig¶ found the secretion was only slightly lessened. It is certain that the hepatic artery may indirectly furnish the supply of blood necessary for the secretion; for although, if the Vena Portæ be suddenly tied, the flow of bile is immediately stopped, and death ensues in the course of a few hours, yet if the obliteration be slowly effected, either by the gradual tightening of a ligature,** or, as occasionally happens, from disease, the secretion of bile still continues, though in diminished quantity and of more watery quality. In such instances it probably proceeds from the blood of the hepatic artery, the capillaries of which discharge themselves into the lobular plexus of veins, and in cases of malformation have been actually observed to pass into the ramifications of the umbilical vein, forming a plexus in the lobules that exactly resembled the ordinary portal plexus.†† Its

†† Such, at least, was found to be the case in the only instance in which the Liver was examined with sufficient care. See Kiernan, loc. cit.

secretion after such slow obliteration of the Venæ Portæ may also sometimes be due to the presence and enlargement of the accessory Venæ Portæ, which have been noticed by Sappey.* According to Bernard,† the engorgement of the Venæ Portæ consequent upon its slow obliteration is relieved by the presence of small anastomotic branches, with the Renal Vein corresponding to the Venous system of Jacobson found in the lower Vertebrata‡.—The fact that the secretion of Bile is normally formed, in great part at least, from *venous* blood, has been commonly connected with the hydrocarbonaceous nature of its chief components, which must exist (it is considered) in larger proportion in such blood than in that of the arteries. But it must be borne in mind that the urinary excretion, which is undoubtedly formed at the expense of the products of the disintegration of the tissues, is secreted from arterial blood; and since the bile is, as it were, the *complement* of the urine (the ultimate components of the two together making up the composition of blood), there seems no reason why arterial blood should not furnish its materials as abundantly (or nearly so) as venous. The real explanation of the peculiar relation of the Liver to the venous circulation is probably to be found in the action of the organ upon the matters newly absorbed into the circulation from the alimentary canal. That this action is not only assimilative, as already shown (CHAP. VI. Sect. 3), but is also to a certain extent depurative, appears from the fact that the liver tends to remove from the blood, and to store up in its own substance, certain foreign matters of an injurious kind—such as copper, arsenic, iron, manganese, lead, antimony, and potassium iodide—which have found their way into the tributaries of the portal system. This seems also to be the case with respect to pus, which, when taken-up from ulcers in the intestinal walls, is stopped in the liver, and not unfrequently gives rise to abscesses in its substance.§

348. There is strong reason for believing that the chief constituents of the Bile are elaborated in the liver itself, and are not preformed in the blood, since, although the tests for biliary acids are far more delicate than those employed for the detection of urea, no trace has been discovered of them in the blood of animals whose livers have been extirpated, though it might be expected that, if like the components of the urinary secretion, they pre-exist in the circulating current, and are merely eliminated from it by the action of the liver, they would accumulate in it when that elimination is checked by the removal of the secreting organ. Some of the constituents of this very complex secretion may undoubtedly be found in other organs or fluids of the body; thus, cholesterin is found in the blood, lymph, most glands, and abundantly in the brain. Taurin is a constant constituent of the lungs and muscles of many animals, and Taurocholic acid is stated by Cloez and Vulpian to exist in the supra-renal capsules. Glycocoll can easily be obtained from hippuric acid, which is constantly present in the urine; and even the colouring matters bilirubin and biliverdin occur normally in the placenta of the dog. Still there can be little doubt that the pigmentary substances and the conjugated tauro- and glyco-cholic acids are formed in the liver itself, and that they are produced at the expense of substances of an excrementitious character, whose retention in the circulating current would be injurious; this being strikingly demonstrated by the disturbance of the functions generally, and especially of

those of the Nervous system, which is consequent upon the suspension of the secreting process. When the suppression is complete, the powers of that system are speedily lowered (almost as by a narcotic poison), the patient suddenly becomes jaundiced, and death rapidly supervenes.* When the secretion is diminished, but not suspended, the same symptoms present themselves in a less aggravated form. The gall-bladder begins to contain bile at about the sixth month of intra-uterine life, and it has been shown by Simon and Frerichs that the *meconium* which is contained in the intestinal canal at birth is chiefly composed of inspissated bile; Kühne,† after referring to the results of various investigations, observes that the bile undergoes the same changes in the intestines as when boiled with acids or alkalies, or when allowed to putrefy. These changes commence in the lower part of the ileum, and are completed in the cæcum and colon. Glycocholic acid, which is decomposed with difficulty, may frequently be found in the fæces of animals, in which it constitutes the chief biliary acid, whilst in the fæces of Carnivora, whose bile is principally composed of Taurocholic acid, only cholalic acid appears. According to Bischoff, man discharges about 50 grains of the biliary acids by the fæces per diem, whilst Voit's estimate gives 170 grains as the quantity daily formed by the liver; 120 grains must, therefore be reabsorbed or otherwise disposed of.—The excrementitious character of the Biliary secretion is very strikingly indicated by its formation during fœtal life; which, as it can then have reference neither to the function of Digestion nor to that of Respiration, must be regarded as having for its purpose to free the blood of matter which would be injurious to it. And this matter can hardly arise from any other source than the 'waste' of the tissues (consequent upon the limited duration of their existence), which takes place even when the life of the organism is most purely vegetative.

349. From what components of the Blood the materials of the biliary secretion are immediately derived is a question that cannot yet be quite satisfactorily answered. The close resemblance in composition between the resinous acids of bile and the ordinary fats (especially olein), naturally suggests the idea that they are drawn from the fatty matters of the blood; an opinion which was supported by Lehmann on the grounds—first, of the diminished proportion of fat contained in the Hepatic as compared with the Portal Venous blood; secondly, of the increase in the quantity of bile observed after rich fat food; and, thirdly, of the emaciation which occurs in animals as a consequence of the formation of a biliary fistula, in spite of an abundant supply of albuminous food. It must be acknowledged, however, that there are various objections to this view, both physiological and chemical. Thus, it is maintained by Bidder and Schmidt that the flow of bile is not increased by a predominance of fat in the food, and that animals fed exclusively on fat do not secrete more bile than those entirely deprived of food: whilst it has been found by Nasse that it is to the presence of a large amount of albuminous compounds in the food that any great augmentation in the secretion is due.‡ Whatever may be their mode of origin, there is every reason to believe that the production of the components of bile is a necessary part of those processes of retrograde metamorphosis, by which the materials of the effete tissues are removed from the

* See Prof. Alison in "Edin. Med. and Surg. Journ.," vol. xliv.; and Dr. Budd, op. cit., chap. iii. Austin Flint ("Physiology of Man," vol. iii. p. 288, *et seq.*) has suggested that it is the cholesterin which acts as the poisonous agent, and has proposed the term 'cholesteræmia' for this form of blood-poisoning; but the observations of Feltz and Ritter (Robin's "Journal de l'Anatomie," 1875, p. 171) on the effects of the injection of cholesterin are opposed to Dr. Flint's view.

† "Physiol. Chemie," 1868, p. 103.

system. The increase of the secretion after each ordinary ingestion of food (§ 125), and its marked and progressive diminution in animals entirely deprived of aliment (as determined by MM. Bidder and Schmidt), indicate that the secretion takes place, in part at least, as a reflex act, occurring in response to the stimulation of the gastric and intestinal nerves; in part also to the absorption of digested aliment by the radicles of the Vena Portæ and its conduction to the liver; and, lastly, and perhaps chiefly, to the increased flow of blood to the organ which follows the ingestion of food.* The experiments and observations of Schiff,† Lussana,‡ and others have demonstrated that a constant circulation of bile takes place in healthy conditions, so that a large portion of that which has been secreted by the liver and discharged into the intestines is reabsorbed from thence and again separated by the liver. They found that on inserting a canula into the gall-bladder, after tying the ductus communis choledochus, the discharge of Bile was considerable for the space of half-an-hour, the liver during this period performing the part of a secreting as well as of an excreting organ, but rapid diminution then took place in the amount discharged from the canula, because Bile no longer entered, and could therefore no longer be absorbed from the intestine. When, however, Bile was injected into the blood, the quantity eliminated quickly underwent increase, though it again diminished when the additional quantity had been excreted.

350. In regard to the influence of the Nervous system on the secretion of Bile, the results of experiments are contradictory: thus, whilst Pflüger states that no effect is produced on the secretion—in regard to its quantity, at least—by section of the Pneumogastrics, Phrenics, Splanchnics, or Sympathetics, by destruction of the Cœliac Plexus, nor after destruction of all the nerves entering the Porta Hepatis, provided the supply of blood be not interfered with, Röhrig§ found that section of the splanchnics or of the spinal cord, either of which causes dilatation of the abdominal vessels, is followed by increased flow of Bile, whilst, on the contrary, reflex irritation of the cord, (as by stimulating a sensory nerve) by contracting the vessels, diminishes it. The reason of this is that the most important factor in the secretion of Bile is the rapidity of the circulation through the vessels of the abdominal viscera. Irritation of the Spinal Cord is without effect if the splanchnics have been previously divided.‖ In regard to the action of Medicines on the flow of Bile, the observations of Bennett, Rutherford, and Gamgee¶ have shown that Calomel, Corrosive sublimate, and Podophyllin augment the secretion of bile;

* A remarkable and hitherto unexplained circumstance is that bile obtained from the gall-bladder in man and the dog contains about 10 per cent. of solids, whilst bile obtained from biliary fistula in man only contains from 2·24 to 2·28 per cent. of solids, and in the dog usually only about 3 or 4, or rarely 6 per cent.

† Pflüger's "Archiv," 1870, p. 598. The observations of Rosenkranz ("Verhandlungen d. Phys. Med.-Gesellsch in Würzburg," Band xiii. 1879, p. 224) support the statements of Schiff, and show that the reabsorption of the biliary salts is rapid, being easily demonstrable within an hour. They are in opposition to the statement of Tappeiner ("Amtlicher Ber. der 50 Naturforscher Versammlung in München," p. 237), that Glycocholic acid is reabsorbed in the jejunum and ileum, whilst the taurocholic acid is only taken up in the ileum. Rosenkranz thinks, however, that but little of the absorbed salts reappear in the bile, they rather seem to disappear in the blood after having effected, or in the act of effecting, changes in the blood corpuscles which lead to the production of fresh biliary salts.

‖ See Heidenhain, "Centralblatt," 1867, p. 662, and 1868, p. 710; and Munk, Pflüger's "Archiv," Band viii. p. 151, who think that there is a primary increased flow of bile on irritation of the spinal cord, which is due to the contraction of the muscular fibres they believe to be present in the biliary ducts. ¶ "Brit. Med. Journ.," 1869, vol. i. p. 411.

and those of Rutherford and Vignal,* that the same effect is produced on the secretion in the dog by Aloes, Rhubarb, Colchicum, Iridin, Ipecacuanha, Colocynth, Phytolaccin, dilute nitro-hydrochloric acid, ammonium and sodium benzoate, sodium salicylate, and ammonium phosphate. The biliary secretion is not materially modified in quantity by Morphia, Alcohol, Calomel, or Potassium iodide. Violent purgation usually diminishes the secretion of bile, and many substances, as magnesium sulphate and scammony, are powerful stimulants of the intestinal glands, but have little action on the bile. Acetate of lead is one of the few substances that depress the secretory action of the liver.

351. But besides the secretion of Bile, it appears that another purpose is fulfilled by the Liver—the production of an amyloid substance termed Glycogen; and we shall now proceed to consider the chief facts which have been ascertained with reference to this so-called 'Glycogenic function of the Liver.' It had long been well known that Vegetables were capable of producing Starch and Sugar from the inorganic materials of their food, but the presence of a form of Starch—Cellulose—as a constituent of the animal body, in the test of one of the Tunicata announced by Dr. Schmidt, and corroborated by the observations of Löwig and Kölliker,† was considered to be only interesting because it destroyed what had till then been looked upon as one of the most important means of distinguishing the tissues of the animal from those of the plant. In 1848, however, Bernard‡ observed that, whilst the Blood of the system generally, and that of the Vena Portæ in particular, in an animal fed exclusively on meat, appeared to be destitute of Sugar, a very notable quantity could be detected in the blood of the Hepatic Vein and right heart—that is to say, in the blood which had passed through the Liver. The question which arose—whether the sugar was formed by, or was only stored up in, the liver—was answered by showing that after the liver had been thoroughly freed from blood by the injection of water into the portal vein, sugar was formed anew; and in the course of this investigation it was incidentally shown that the amount of sugar obtainable from the liver increases, within certain limits, with the time after death at which it is examined. He immediately inferred that a new function, the formation of Sugar, was to be attributed to the Liver; that the sugar so produced was thrown into the circulation, and then, by undergoing combustion, ministered to the maintenance of animal heat. He was supported in this view by the authority and analyses of Lehmann,§ who suggested that the Sugar might proceed from the decomposition of albuminous compounds, since there was a smaller quantity of albumin in Hepatic as compared with Portal Venous blood; and there were also good chemical grounds for supposing that albumin might split up into nitrogenous compounds, represented by the conjugated biliary acids (which also contain the sulphur), and into non-nitrogenous compounds represented by Starch, Glycogen, and Sugar. Schmidt (of Dorpat) conceived that the Sugar might result from the decomposition of the fatty substances; whilst Frerichs thought that the albuminous substances might break up into Glucose and Urea. Bernard|| himself, however, was disposed to consider that Bile and Sugar were produced in the Liver independently of one another; first, because the formation of Sugar was most active at a much earlier period after food than that of Bile; and, secondly, because in one of the Mollusca (Limax flava) he found that the liver

secreted sugar and bile alternately, the former during, the latter after, digestion. The observations of Bernard, from their novelty and interest, attracted the attention of many chemists and physiologists, and it was soon shown that sugar, though in comparatively small proportion, was frequently present in the blood of the general circulation, and of the Vena Portæ, as well as in that of the Hepatic vein. Thus, Chauveau* found in the arterial blood of a Horse, which had fasted for six days, 0·6 parts in 1000 of Sugar, and in the systemic venous blood, 0·5 parts in 1000. Colin also detected traces of Sugar in the Chyle and Lymph. Very careful investigations were soon made† to determine the proportion of Sugar in the Liver, and in the blood drawn from different parts of the body in animals under different circumstances, the general results of which appeared to be that sugar existed in the arterial blood of the Dog in the proportion of about 1·5 per 1000; in the Vena Cava inferior, below the renal veins, 0·54 per 1000; and in the Vena Cava inferior, above the diaphragm—*i.e.*, above the entrance of the Hepatic vein, 1·12 per 1000. In Herbivora, the quantity of Sugar in the blood of the Hepatic vein amounted to about 1 per 1000 during fasting, and from 2 to 6 per 1000 at a period of full digestion, whilst the mean quantity found in the liver substance was found to be from $\frac{1}{2}$ to $2\frac{1}{2}$ per cent. The much larger proportion of sugar obtained from the liver of herbivorous as compared with carnivorous animals, especially after a meal containing much amylaceous or saccharine material, naturally led to the supposition that these substances are derived from the aliment, and are merely deposited in the tissue of the liver; and we accordingly find Figuier‡ and Sanson§ arriving at the conclusion that vegetables alone are capable of producing starch, a part of which, when formed, is applied by the plant to the nutrition of its own tissues, whilst another part, stored up in cells, becomes subservient to the nutrition of Herbivorous animals. In these, again, a portion of the starch is consumed in the vital processes, whilst another portion is distributed to the tissues, being especially abundant in the liver; and to this source they believed the sugar contained in the blood of Carnivora was traceable. This view, however, became untenable when it was shown that in animals fed exclusively for months on ordinary butchers' meat, in which only traces of dextrin were present, the presence of sugar in the liver, though in much smaller quantity, could readily be demonstrated. In such cases it was obvious that the sugar could not be derived directly from the aliment, but must have been the result of metamorphoses taking place in the economy.

352. In the meanwhile Bernard, pursuing his investigations, was struck with the circumstance, that if the vessels of the Liver were thoroughly cleared of Sugar by the injection of water, a fresh supply of that substance could be obtained, after the lapse of a few hours, upon re-injection; showing not only that the production of sugar must be external to the vessels, and in the very substance of the organ itself, but also that it is capable of taking place quite independently of all vital action. From a consideration of these facts, he was led to inquire whether there might not be some substance formed by and pre-existent in the hepatic tissue, from the metamorphosis of which the sugar proceeded; and he, coincidentally with Hensen‖ and Pavey,¶ was soon suc-

cessful in obtaining a peculiar substance possessing properties intermediate between those of starch and dextrin, and capable, under the action of ferments, of being readily converted into sugar, and of ultimately undergoing alcoholic or lactic acid fermentation. This substance was termed Glycogen by Bernard; Hepatin, or Amyloid substance, by Pavy; and Zo-amylin by Rouget. It exists in an amorphous state in the cells of the Liver, being especially abundant in those adjacent to the branches of the hepatic vein. It belongs to the group of colloidal or non-diffusible bodies (Pavy.) The great influence exercised by the nature of the food on its amount has been clearly shown by Dr. Pavy,* M'Donnell, and Tscherinoff.† Dr. Pavy found, on analysing the livers of dogs fed exclusively on animal diet, about 7 per cent. of amyloid substance; whilst in those fed on meat and sugar it amounted to 14·5 per cent.; and in those fed on vegetable diet alone to 17 per cent. In cases where animals were fed on starch and sugar, the livers were pale and pulpy. No amyloid substance was present in animals dying of starvation or wasting disease.‡ The amount of Glycogen in the Liver of those animals in which the tissue of the organ is compact is much less than in those in which it is loose. In the Horse, for example, it is at least three times less than in the Rabbit. In Fowls, Brücke found it might reach the high proportion of 12 per cent. of the total weight of the Liver. In rabbits submitted for several days prior to death to different dietaries, it has been found§ that cane, milk, and grape-sugar and starch always leads to an increased per-centage of amyloid substance in the Liver, in from six to eight hours after administration,‖ but no increase occurs after the administration of mannite, lichenin, inosit, gelatin, or fats;¶ this organ appearing to seize upon these substances and store them up, so that the sudden entry of a large quantity into the general circulation is prevented. If, however, a very considerable quantity of sugar be introduced into the stomach, especially if it be empty (as it commonly is in the dog), it is quickly absorbed, and though conveyed to the liver, this organ is unable to metamorphose the whole of it, and the portion which escapes entering the general circulation is discharged by the Kidneys, when the proportion exceeds 3 per cent. of the blood. The same quantity of Sugar may be disposed of without producing diabetes if it be ingested slowly, or when the stomach is full (as it commonly is in rabbits), and thus Bernard accounts for the differ-

* "Phil. Trans.," 1860, p. 604.

† "Sitz. d. k. Akad. zu Wien.," Band li. 1865, p. 412. See also Dock, Pflüger's "Archiv," Band v. p. 571.

‡ This is not in accordance with Bernard's experiments ("Revue Scient.," t. viii. 1872–73, p. 1155), who found glycogen to be constantly present, even after prolonged fasting. Dock states that when in consequence of inanition all glycogen had disappeared from the liver, the ingestion of sugar into the stomach caused the appearance of large quantities in the liver in the course of a few hours, but no such effect was produced in rabbits by the ingestion of albumin. See Tiegel, idem, Band vi. p. 249. The differences in the amount of glycogen found by different observers under apparently similar conditions may perhaps be due to the circumstance pointed out by v. Wittich ("Centralblatt f. d. Med. Wiss.," 1875, p. 117), that the formation of glycogen does not take place with equal energy in all parts of the liver, some producing it more abundantly than others. Seegen, Pflüger's "Archiv," Band xix. 1879, p. 122, has demonstrated that the sugar formed in the dead liver is grape-sugar. Finn ("Würzburg. Phys.-Med. Verhand. N. F.," Band xi. p. 92) finds that glycogen differs somewhat according to the nature of the food on which the animal is fed. Glycogen, from a diet of grape-sugar, rotated light 173°, levulose 168°, glycerin 160°, albumin 163°.

§ See Luchsinger, Pflüger's "Archiv," Band viii., and Salomon, Virchow's "Archiv," Band lxi. p. 352.

‖ Konjkoff, "Diss." Petersburgh, abstracted in "Centralblatt," 1876, p. 734.

¶ v. Mering, Pflüger's "Archiv," Band xiv. p. 274.

ence in regard to the appearance of Sugar in the urine after the administration of the same quantity to dogs and rabbits.* The explanation that may be afforded of this is, that when sugar or glycose is rapidly ingested, it traverses and is expelled from the system unchanged, but when introduced more slowly, the liver formed has time to act upon it, and convert it into Glycogen, which is stored up in the Liver. Although, as the foregoing experiments show, the amyloid substance is much more abundant in the livers of animals fed on starch and sugar, from which, therefore, it doubtless in part proceeds, it must not be overlooked that it is also present in animals confined to a pure meat diet; in which case it is probable that it proceeds from the disintegration of albuminous compounds into hydrocarbonaceous and nitrogenized substances,† or it may be derived from the glycogen present in the flesh, used as food. In granivorous and herbivorous animals, as in Fowls and Rabbits, the albuminous compounds do not appear to be well adapted for the production of glycogen. Thus Weiss‡ found only traces of Glycogen in the liver of fowls fed for a fortnight on flesh and fibrin, and Dock found none in rabbits fed with white of egg. The same conclusion may be drawn from the fact that the quantity of glycogen in the liver of animals starving to death, and when therefore they are living on animal diet, is greatly reduced. Very different times are required for all the glycogen to disappear from the liver as a result of fasting in animals of different species, and even in different animals of the same species. Thus Luchsinger§ found from 4—6 days elapsed before it was reduced to a minimum in rabbits, whilst others‖ give $2\frac{1}{2}$ to 3 days. In dogs it is absent after from 14—21 days. In frogs after 2 days. Yet in hybernating animals the liver, after protracted hybernation, still contains a large amount of glycogen.¶ In 1859, Bernard** detected the presence of amyloid substance in the placenta of ruminants—in which, or rather, as has been since shown, in patches of cells lying on the inner surface of the amnion—it exists in considerable quantities. Shortly afterwards, Rouget†† discovered it in various embryonic cellular tissues, as in the epithelium of the skin, and of the alimentary and genito-urinary mucous membranes. It is remarkable that it is not found in the liver till its histological development is completed, or until about the middle of intra-uterine existence. It is present, except after long fasting, in the muscles, the proportion amounting in rabbits and frogs to about 0·4 or 0·5 per cent.‡‡ It has also been found in the testis, in the lungs and kidneys§§ and in pus.‖‖ It is not found in the bones nor in the nerves, though Jaffe has observed the presence of an amyloid substance in the brain. Amyloid substance has been found also in the bodies of several invertebrate animals, as in the snail (Bernard),¶¶ tape and round worm,*** cockle, scallop,††† mussel, oyster;‡‡‡ and the yellow cells of Radiolaria, but in these instances it appears to have little ten-

dency to become transformed into sugar. The "corpora amylacea" of Virchow, observed as pathological formations in the kidney, spleen, and other organs, and at one time considered to be identical with amyloid substance, differ from it essentially in containing nitrogen.*

353. After the presence of an amyloid material was shown to be constant in the liver, and to precede the formation of sugar, it was supposed that some *ferment* was requisite by which, either in the hepatic cells themselves, or after the absorption of the starch into the blood, its conversion into sugar could be rapidly effected. Many efforts were made to ascertain the source of this ferment; and the spleen, thymus, thyroid, supra-renal, salivary, and pancreatic glands were successively extirpated by Schiff,†, without, however, his being able to determine whether any of them were instrumental in its formation. Bernard,‡ Hensen, and Cohnheim§ maintain that the ferment is thrown down with the amyloid substance on the addition of alcohol to the cold aqueous infusion of the liver; that it can be obtained by the same process as that employed to isolate ptyalin, which it resembles in properties; that it is rendered inoperative by boiling; and, finally, that it is contained in ordinary arterial blood, and in the blood of the vena portæ, the addition of such blood to a solution of glycogen effecting its conversion into sugar. The necessity for the existence of this ferment has been rendered doubtful by the investigations of Dr. Pavy,‖ whose experiments have led him to the following conclusions:—1. That the liver normally and *during life*, whatever may have been the nature of the food, contains little or no sugar, but a considerable proportion of amyloid substance; since if it be removed from the body instantly after death, and subjected to the action of caustic or carbonated potash or soda, or of extreme cold, no saccharine reaction can be obtained, though the presence of the amyloid substance can easily be shown. 2. That, *during life*, there is under ordinary circumstances very little difference in the amount of sugar contained in different specimens of blood, whether withdrawn from the systemic arteries or veins, the portal vein, or (by means of a catheter introduced through the jugular vein)¶ from the right auricle; the latter, of course, containing a large proportion of hepatic venous blood: the quantity of sugar present in all instances being extremely small, and varying from 47 to 73-1000ths of a grain per cent. 3. That *during life*, therefore, very little amyloid substance is taken up by the blood in its passage through the liver, as indeed might be anticipated from its low power of dialysing through animal membranes. On the contrary, after death, frequently from various disturbing causes during life, such as violent muscular action or embarrassment of the respiration, a conversion of the amyloid substance into sugar takes place in the substance of the liver itself, and the sugar so formed then quickly appears in the blood, often to so great an extent as to occasion diabetes. Moderate heat promotes the post-mortem formation of sugar from glycogen. The liver of a rat contained 2 per cent. of glycose three hours after death, and 5·2 per cent. after twenty hours.** Dalton found 5 seconds after death 1·8 per 1000 of glycose in a specimen of liver, 15 minutes after death 6·8 per 1000, and an hour after 10·3 per 1000.

354. At a very early period of the history of the glycogenic function of the Liver, it was found that the formation of sugar could be influenced through *the nervous system*. Bernard, for instance, observed that when the floor of the fourth ventricle, between the origin of the Pneumogastric and Auditory nerves (see Fig. 180) was pricked with a needle,* so great an increase in the quantity of sugar generated was effected in the course of an hour that was discharged by the urine, a condition of diabetes, lasting at most for twenty-four hours, being established. If, however, the same point be pricked after the branches of the sympathetic to the liver, which chiefly proceed from the splanchnics, have been divided, or the liver be removed entirely, no diabetes occurs.† Nor does any diabetes follow pricking the floor of the fourth ventricle in winter frogs, or in animals kept long fasting, or which have been supplied with arsenious acid in their food, in all of which the liver is destitute of glycogen. Diabetes can be induced by irritation of the central extremity of the divided vagus and by stimulation of any part of the nerve centres between the optic thalamus and the sixth dorsal vertebra,‡ and also by section of the splanchnics,§ which led Schiff to admit a form of diabetes from stimation, and a diabetes from paralysis of the hepatic vaso-motor nerves. Eckhard found that section of the inferior cervical ganglion was always followed by marked diabetes, and he arrived at the conclusion that the effects of pricking the fourth ventricle were transmitted through the inferior cervical and the upper thoracic ganglia. Diabetes was produced by Pavy both after division of the sympathetic cord in the neck and of the sympathetic plexus accompanying the vertebral arteries. The cause of the diabetes in these instances is the paralysis of the vaso-motor nerves, similar to that produced by direct injury to their centres, as when the fourth ventricle is punctured, or possibly by reflex irritation, as when the Pneumogastrics are irritated and there is a consecutive dilatation of the branches of the hepatic artery, and a more rapid circulation of blood through the liver. The importance of the free circulation of the blood through the liver is shown by the fact that if the vena cava in a frog be tied just below the liver, the blood is diverted by anastomoses into the vena portæ, and the liver becomes greatly congested, the result of which is that sugar appears in the urine. The vaso-motor nerves for the liver arise for the most part from the vaso-motor centres in the medulla oblongata, and descending through the cord, leave this by means of fibres which

Fig. 180.

To show the position of the punctures which most readily produces glucosuria, the lobes of the cerebellum are separated; below are seen the restiform bodies, the divergence of which bound the apex of the calamus scriptorius and the fourth ventricle. The puncture p' produces glycosuria, the puncture p glycosuria with polyuria, and a puncture a little higher up than p, albuminuria.

accompany the vertebral artery and enter the lower cervical ganglia. Thence they proceed contained in two fasciculi, one of which passes on each side of the subclavian artery, forming the annulus of Vieussens to the first thoracic ganglion, and so through the successive ganglia of the sympathetic to the splanchnics and to the cœliac ganglion, and finally along the hepatic vessels to the liver. The experiments of Eckhard* render it probable that in some instances the fibres descend through the cord to a lower level than that of the vertebral artery before they emerge to enter the splanchnics. As section of the hepatic vaso-motor nerves at any point between the fourth ventricle and the liver causes vaso-motor paralysis and increased flow of blood through the liver, such section ought to be always followed by glycosuria, but this is by no means the case, and a rational explanation of its non-occurrence has been given by Cyon and Aladoff to the effect that although the section does really produce vaso-motor paralysis of the vessels of the liver, yet that the current of blood is not materially increased, because the same section, if made high up, coincidentally paralyses the vessels of the abdominal viscera which, owing to their great size, imprison as it were a large quantity of the blood, and so prevent any material change in the quantity of blood passing through the hepatic vessels. It has been found by Mayer that when grape sugar is injected into the blood, and the cord is divided between the fifth and sixth cervical vertebræ, the formation of glycogen by the liver is materially diminished, though the sugar is retained in the blood and applied to tissue changes. When the section of the cord is made between the seventh cervical and first dorsal vertebræ, the formation of glycogen in the liver is augmented without any decrease in the quantity of sugar contained in the blood. Lastly, section of the cord between the second and third dorsal vertebræ causes decreased glycogen formation in the liver and reduces the quantity of sugar in the blood.† In regard to the influence of the Pneumogastrics on the secretion of sugar by the liver, it has been ascertained that section of one of these nerves in the neck, or the stimulation of the peripheral cut surface is without effect. Section of both pneumogastrics diminishes the production of sugar. If, however, the *upper* cut surface of one or both pneumogastrics be stimulated, sugar rapidly makes its appearance in the urine, which appears to be due to a reflex influence conducted centripetally by the nerve, and causing paralysis of the vaso-motor centre. The pneumogastrics are, therefore, the sensory centripetally running nerves of the liver, and it has been suggested by Bernard‡ that the sympathetic presides over the secretion of sugar, and the pneumogastric nerve transmits to it the stimulus of the air, or, in other words, the oxygen of the air normally induces the formation of sugar through the pneumogastric and sympathetic nerves. It may here be remarked that the close relationship of the secretion of bile with the formation of glycogen is demonstrated by the observations of Dr. Legg,§ who has shown that after ligature or complete obstruction of the Hepatic ducts, glycogen is no longer formed by the Liver, and that puncture of the fourth ventricle fails to produce diabetes.

355. The influence of medicinal agents upon the glycogenic function of the Liver has received but little attention, though various substances are known to be capable of inducing diabetes. Cozé|| found the proportion of sugar nearly doubled both in the liver and in arterial blood after the adminis-

|| "Comptes Rendus," 1857.

tration of morphia. Pavy* observed well-marked diabetes in animals after the administration of phosphoric acid, and also after poisonous doses of strychnia, when the circulation was maintained by artificial respiration. Harley obtained the same result in himself after eating freely of asparagus. Certain poisons, as Curare,† cause considerable increase in the quantity of glycogen in the blood and in the muscles, and it has been suggested that this is attributable to the paralysed muscles being unable to utilise the sugar formed in the liver. On the other hand, no glycogen is contained in the liver of animals kept motionless by bandages, notwithstanding an abundant supply of grape sugar.‡ The excess of sugar after the use of curare is discharged by the urine. It is remarkable that a few hours after the injection of from 3-10 grammes of glycogen into the veins hæmaturia supervenes.§ Glycogen, therefore, appears to be a solvent for the blood corpuscles. Achroodextrin also makes its appearance in the urine. Ewald‖ observed diabetes in Rabbits after the subcutaneous injection of nitro-benzole. The administration of large doses of caustic potash, or of carbonate of soda, is stated by Dr. Pavy to prevent the occurrence of diabetes under circumstances in which it would otherwise have been induced. The proportion of Glycogen in the Liver is diminished after the administration of arsenic and of amyl-nitrite.¶ Diabetes may be produced by disturbance of the *respiratory process*. Thus, it occurs in the Asphyxia caused by poisoning with carbonic oxide gas (Schiff), and Harley observed it in animals under the influence of ether, chloroform, liquor ammoniæ, and methylated spirit.** Reynosa†† produced it by making animals respire the vapours of benzoin and acetoin, and found that it followed asphyxia, slowly produced by the inhalation of carbonic, hydrocyanic, and sulphuretted hydrogen gases. Disturbances in the *circulation* of the blood have been found to exert a very distinct influence on the amount of sugar that can be obtained from the Liver. Thus, Bernard‡‡ found that the liver of a dog contained 3·5 parts of sugar in every 1000 parts, but on removing the liver from the body, or on arresting the circulation through it, the amount rose in the course of five minutes to 8 parts, and after twenty-four hours to 32 parts per 1000. Schiff, again, found that retention of the blood or retardation of the blood-current in any part, such as ligature or compression of the larger vessels, will lead to diabetes. Tieffenbach, however, found that the amount of sugar was increased by arrest of the circulation through the aorta or vena portæ. The experiment made by Winogradoff,§§ and already referred to, shows conclusively that the sugar is formed directly or indirectly by the liver, for when diabetes has been produced by the puncture of the floor of the fourth ventricle or by curare, it at once ceases on ablation of the liver, and a similar conclusion may be arrived at by puncturing the fourth ventricle in an animal to which arsenic has been administered for some time, for this drug has been found to prevent the formation of glycogen in the liver; and in consequence of the absence of glycogen in the liver, sugar is not produced in sufficient quantity to lead to its elimination by the kidneys. Chandelon‖‖ found that, after ligature of one common iliac artery in rabbits, the muscles of the operated side presented, in from

17—24 hours after the operation, a diminution amounting to 37—77 per cent. in the quantity of glycogen they contain as compared with those of the sound side. After section of the sciatic nerve, on the contrary, there was an increase of from 5—172 per cent. Hence he thinks muscular action is attended with glycogen consumption. Yet it must be observed that muscles may perfectly preserve their vital properties when no trace of glycogen can be shown to be present in them;* hence this substance can scarcely constitute the direct source of their activity.

356. The use of the amyloid substance developed in the Liver is involved in the greatest obscurity. By the earlier observers it was thought that it was immediately reconverted into sugar, and undergoing combustion in its passage through the Lungs, became subservient to the maintenance of animal heat. Various arguments have, however, been justly urged by Dr. Pavy against this view, and he is himself disposed to regard its production as representing the first step of assimilation of the *starchy* and *saccharine* elements of our food; and as these elements are known to lead to the formation of fat, he thinks there are grounds for believing that amyloid substance occupies an intermediate position between the two. The process of assimilation, he believes, may go on to the production of fat in the liver, or it may be that it stops short at the formation of another principle which escapes from the liver, and is elsewhere transformed into fat, or into the resinoid matter of the bile. In accordance with this view are the researches of Tscherinoff, who, obtaining similar results to those of Dr. Pavy in regard to the amyloid substance, noticed also that the use of food containing much hydrocarbonaceous matter, as sugar, greatly increased the proportion of *fat* in the liver. Two theories have been advanced to explain why the amount of glycogen in the liver is increased after the use of the carbo-hydrates. On the one hand, it may be said that the carbo-hydrates are more or less completely converted into glycogen within the liver, and that they are stored up in that organ;† and, on the other, it is maintained that the carbo-hydrates being readily oxidizable seize upon the oxygen of the blood and spare the glycogen derived from some other source.‡ The probabilities seem in favour of the former view. In regard to the origin of glycogen from *oleaginous* compounds, the experiments of Bernard, M'Donnell, and Luchsinger with fat dietaries seemed to show that this diet is unfavourable to the formation of glycogen; and even Salomon, whose recent experiments§ are not quite in accordance with those of his predecessors, shows that the proportion of glycogen is very much less on a fat than upon a saccharine diet, and about half as much as upon a gelatin diet. The concordant results of Weiss, Luchsinger, and Salomon show that glycogen is abundantly formed when glycerin is either administered alone in a diluted state or given with the food. Experiments with soap diet have been undertaken by Salomon, but have not enabled him to determine whether the glycogen in neutral fat diet proceeds from the glycerin it contains. The circumstance that the blood which enters the Liver is rich in *fibrin* and *albumin*, whilst that which leaves it is poor in these materials, has led Dr. M'Donnell to suggest it as probable that these materials break up

* See Luchsinger, Pflüger's "Archiv," Band xviii. p. 475.

† See Pavy, loc. cit.; Tscherinow, loc. cit.; Dock, Pflüger's "Archiv," Band v. p. 57.

‡ Scheremetjewski (Ludwig's "Arbeiten," 1869, p. 154) and Weiss ("Sitz. d. Wien Akad.," Band lxvii. abth. 3) advocate this view, on the ground that after the administration of glycerin the proportion of glycogen in the liver is notably increased, glycerin being a substance not likely to be converted into glycogen. Both Kühne and Luchsinger (Pflüger's "Archiv," 1873, Band viii. p. 289) have shown that this is an assumption unwarranted by facts.

§ Virchow's "Archiv," Band lxi. 1874, p. 354.

into secondary hydrocarbonaceous compounds which are partly eliminated by the bile ducts and are partly stored up as glycogen; and into nitrogenous compounds which reunite with the hydrocarbonaceous amyloid substance, and leave the liver as a newly-formed protein compound, partly perhaps as globulin, and partly as a material resembling casein or albuminose. Dr. W. Ogle* subsequently advanced a similar view, holding that before leaving the liver glycogen unites with some albuminous compound which enters the blood and is transferred to the muscles, where it undergoes decomposition with lactic acid and myosin: the former by its combustion yields muscular force, the latter is returned to the circulation to become again the carrier of a fresh portion of glycogen. That this is its destination he thinks is supported by the fact that muscle naturally contains a not inconsiderable amount of glycogen, as well as by the circumstance that this disappears or is greatly reduced when this tissue is brought into action;† and, lastly, it is in harmony with the fact that glycogen is abundant in most of the tissues of the embryo in which but little muscular energy is expended.‡ Gaetghens,§ from experiments with phosphorus on dogs, in which large quantities of fat are formed in the Liver, rising sometimes to 11 per cent., apparently from the metamorphosis of albumen, observes that there is no increase in the amount of glycogen, and is consequently opposed to this view.‖ Taking, however, such information as we at present possess into consideration, we seem entitled to conclude that the Liver exerts a twofold action on the blood which is traversing its capillaries—an assimilative and a depurative. By its operation as an assimilating organ it helps to prepare histogenetic material for conversion into blood and solid tissue, in the course of which it is capable of *producing* and of *storing up* amylaceous and oleaginous material in its cells, both of which are capable of being called upon for the maintenance of muscular force and of animal heat; whilst by its depurative action it frees the blood from the protein compounds which are destined to undergo retrograde metamorphosis, as being either superfluous or effete. A portion of these is again, in all probability, applied to the production of amyloid substance and fat; whilst the remainder, containing the nitrogen and sulphur, though a waste product, is in the form of the bile made subservient to digestion, and the introduction of fresh material into the blood before its final discharge from the body.

3. *The Kidneys.—Secretion of Urine.*

357. The Kidneys are a secondary urinary apparatus, developed from the Wolffian or Excretory duct of the primordial kidney. They cannot be regarded as inferior in importance to the Liver, when considered merely as Excreting organs; but their function only consists in separating from the blood certain effete substances which are to be thrown-off from it, and has no direct connection with any of the nutritive operations concerned in the introduction of aliment into the system. The following are the points in the minute structure of these organs which are of most importance in their Physiological relations:¶—Their glandular and vascular elements are embedded in a stroma

composed of connective-tissue continuous with the deep layer of the same tissue covering the surface of the organ. It consists of long fusiform cells, or Inoblasts, which stretch inward to the pyramids, and give a general support to the other tissues. A section of the kidney shows that it consists of an external or *cortical* portion, and an internal striated, and usually darker, *medullary* portion. Of these two parts the cortical is by far the most vascular, and the plexus formed by the tubuli uriniferi seems here to come into the closest relation with that of the sanguiferous capillaries, so that it is probably the seat of the greater part of the process of secretion; whilst the medullary is principally composed of tubes, passing in a straight line from the cortical portion towards their point of entrance into the ureter. The tubuli uriniferi commence in dilatations, named Malpighian Capsules (*d*, Fig. 181; *a*, Fig. 183), and terminate, after joining in their course, with others on the apex of the pyramids. The length of a tubulus is estimated at two inches. The total number of Capsules is about 500,000 in each kidney, and about 1000 tubuli join to form one papillary duct. If the course of a tubule be followed from its commencement in the capsule of Malpighi, it is found in the first instance to form a short neck to the capsule (*a*, Fig. 183), this part being lined by dark granular flattened epithelium. The tube then widens (*e*, Fig. 181; *b*, Fig. 183), and, still lying in the cortical substance of the kidney, becomes exceedingly tortuous, and is lined by cubical epithelium. It now forms a remarkable loop running towards the apex of the pyramid (*ff*, *gg*, Fig. 181), and returning to the cortical sub-

stance. This loop was first recognised by Henle, after whom it has been named "the loop of Henle." It is throughout narrower than the tortuous portion, but the recurrent limb of the loop (*g*, Fig. 181; *b*, Fig. 182) is wider than the descending limb (*f*, Fig. 181; *c*, Fig. 182). The latter portion is lined by transparent pavement epithelium, the former by thicker, more granular, and cloudy epithelium, containing spherical nuclei. A short, rather tortuous portion of the tubuli (*h*, Fig. 181) succeeds, named the connecting canal.* Here

Fig. 182.

the tubule widens again, and is lined by transparent cubical epithelium; continuing to enlarge, it opens into one of the collecting tubes (*a*, Fig. 181), which joins with another to form a larger one, and then again with another (*c*, Fig. 181), until by repeated junctions the large ducts of the papillæ are formed. The collecting tubes are lined by cubical epithelium, which gradually become more columnar with elliptical nuclei in the papillary tubes. The papillary ducts have a diameter of about 1-80th to 1-125th of an inch, but, at a distance of about 1-5th of an inch from the apex of the pyramid, they diminish to about 1-300th, and then to about 1-500th, of an inch, which diameter is nearly constant for the collecting tubes. In the papillæ themselves the ducts lose their basement-membrane, and are composed of the cells alone.† On examining one of the Corpora Malpighiana (*a*, Fig. 183) with a high magnifying power, it is found to consist of a convoluted mass of minute blood-vessels (Fig. 183 *e*), named the *glomerulus*, included in a flask-like dilatation of one of the tubuli uriniferi (Fig. 183 *f*). According to Mr. Bowman, this dilatation proceeds only from the termination of the tubule; and this seems to be usually the case, although it appears not improbable that it may sometimes be a lateral diverticulum, as described by Gerlach (loc. cit.). The inner surface of the Malpighian Capsule is lined by a layer of flat epithelium, the cells of which are distinct in both the adult and the fœtus. A similar layer covers the glomerulus, which is distinct in the fœtus, but only recognisable as scattered polygonal-nucleated

* Also intercalated or secondarily tortuous portion.

† See Heidenhain, "Archiv f. Microscop. Anat.," Band x.; also v. Seng, "Sitz. d. k. Akad. zu Wien.," p. 354.

cells in the adult.* The cells of the neck of the Capsule are furnished with cilia in the Frog and other Reptiles, and may be seen for many hours after death, in very active motion, directing a current down the tube (Hüfner, Mecznikow).

358. The Circulation of Blood through the Kidney presents a very remarkable peculiarity. The supply is derived in man (as in other Mammalia) direct from the *arterial* system; though in Fishes and Reptiles the urinary apparatus is connected, like the biliary, with the *portal venous* system, and even in Birds a portion of its blood is derived from the latter. But although this organ is supplied from the Renal Artery, yet it is not to its proper secretory apparatus that the blood of the artery is distributed in the first instance; for, on entering the kidney, this vessel speedily and entirely divides itself into minute twigs, which are the *afferent* vessels of the Malpighian (Figs. 183, *d*, 184, *a f*). After it has pierced the capsule, each twig dilates, and suddenly divides into two or three short twigs, which subdivide generally into more minute branches, terminating in from twenty to twenty-eight convoluted capillaries, which are collected in the form of a ball (Figs. 183, 184); from the interior of the ball, the solitary *efferent* vessel arises, which passes out of the capsule by the side of the single afferent vessel.† The *efferent* vessels on leaving the Malpighian bodies, separately enter the plexus of Capillaries (Figs. 183, *i*, 184, *p*) surrounding the tortuous portion of the tubuli uriniferi, supplying it with blood; from this plexus the renal vein arises.‡ Thus, there is a striking analogy between the mode in which the tubuli uriniferi are supplied with blood, for the purpose of elaborating their

* Kölliker, "Man. Mic. Anat.," 1860, p. 408. Isaacs, "Trans. of N. Y. Acad. Med.," vol. i. 1857.

† Drasch ("Wiener. Akad. Sitz.-ber.," lxxvi. p. 79) maintains that there are two forms of glomeruli in the kidney, one near the surface with a non-nucleated capsule, the other near the medullary portion of the kidney with a nucleated capsule. The efferent vessel breaks up into the capillary plexus in the former, but runs into the arteriolæ rectæ in the latter.

‡ The reader will find a good summary of the opinions held by Virchow, Ludwig, and others on the course of the vessels, by Dr. Reg. Southey, in the first volume of the "St. Bartholomew Hosp. Reports," p. 177.

secretion, and the plan on which the hepatic circulation is carried on. For as the secretion of the Liver is formed from blood conveyed to it by one large vessel, the portal vein, which has collected it from the venous capillaries of the chylopoietic viscera, and which subdivides again to distribute it through the liver, so the secretion of the Kidney is elaborated from blood which has already passed through one set of capillary vessels, those of the Malpighian tufts; and is then collected and conveyed to the proper *secreting* surface; not, however by one large trunk (which would have been a very inconvenient arrangement), but by a multitude of small ones, the *efferent* vessels of the Malpighian bodies, which may be regarded as collectively representing the portal vein, since they convey the blood from the systemic to the secreting capillaries. Hence the kidney may be said to have a *portal* system within itself.—This ingenious view of Mr. Bowman finds support from the fact, that in Reptiles the *efferent* vessels of the Malpighian bodies (which receive their blood, as elsewhere, from the renal artery) unite with the renal branches of the Vena Portæ, to form the secreting plexus around the tubuli uriniferi. Here, therefore, the blood of the secreting plexus has a double source, the vessels which supply it receiving their blood in part from the capillaries of the organ itself, and in part from those of viscera external to it; just as, in the Liver, the secreting plexus is supplied in part by the nutritive capillaries of the organ itself, which receive their blood from the hepatic artery, and in part by the blood conveyed from the chylopoietic viscera through the Vena Portæ. The absolute quantity of blood traversing the kidneys is wonderfully great, amounting, according to the calculations of M. Brown-Séquard,* to nearly 2000 lbs. per diem.

Distribution of the Renal vessels; from *Kidneys of Horse.* —*a*, branch of Renal artery; *af*, afferent vessels; *m*, *m*, Malpighian tufts; *ef*, *ef*, efferent vessels; *p*, vascular plexus surrounding the tubes; *st*, straight tube; *et*, convoluted tube.

359. The admirable researches of Mr. Bowman on the structure of the Malpighian bodies, and on the vascular apparatus of the Kidney, have thrown great light upon the mode in which the Urinary secretion is elaborated. One of the most remarkable circumstances attending this excretion, in the Mammalia particularly, is the large but variable quantity of *water*, which is thus eliminated—the amount of which bears no constant proportion to that of the solid matter dissolved in it. The quantity of water which is passed off by the Kidneys depends in part upon that exhaled by the Skin, being greatest when this is least, and *vice versâ*: but the quantity of solid matter to be conveyed away in the secretion has little to do with this, being dependent upon the amount of *waste* in the system, and upon the quantity of surplus azotized aliment which has to be discharged through this channel.—The Kidney contains two very distinct provisions for these purposes. The *cells* lining the tubuli uriniferi are probably here, as elsewhere, the instruments by which the *solid* matter of the secretion is eliminated; while it can scarcely be doubted, that the chief office of the Corpora Malpighiana is to allow the transudation of the superflous fluid though the thin-walled capillaries of which they are composed. "It would, indeed," Mr. Bowman remarks,† "be difficult to conceive a disposition of parts more calculated to favour the escape of water from the blood, than that of the Malpighian body. A large artery

* "Journ de la Physiol.," 1858, t. i. p. 305.

† Loc. cit., p. 75.

breaks up in a very direct manner into a number of minute branches; each of which suddenly opens into an assemblage of vessels of far greater aggregate capacity than itself, and from which there is but one narrow exit. Hence must arise a very abrupt retardation in the velocity of the current of blood." The vessels in which this delay occurs lie in a capsule, from which there is but one outlet, the orifice of the tube. "This orifice is encircled by cilia, in active motion, directing a current towards the tube. These exquisite organs must not only serve to carry forward the fluid which is already in the cell, and in which the vascular tuft is bathed; but must tend to remove pressure from the free surface of the vessels, and so to encourage the escape of their more fluid contents."—Here we see the essential difference which exists between the *vital* agency concerned in the true Secreting process, and the *physical* power which occasions fluid exhalation or transudation. This difference is precisely the same as that which exists between the *vital* act of selective absorption, and the *physical* operation of endosmose or imbibition. By Imbibition and Transudation, certain fluids may pass through organic membranes, in the dead as well as in the living body; and this passage depends merely upon the physical condition of the part, in regard to the amount and the nature of the fluid it contains, and the permeability of its tissues.* That the epithelium of the several parts of the urinary tubules have, however, different functions is rendered probable by the different affinities they possess for staining agents,† after carmine injection, for example, the cells of the surface of the glomeruli becoming reddened, whilst those of the contorted portion of the tubuli remain colourless, whilst the opposite obtains with the sulphindigotate of soda. Other observations‡ again tend to show that albumin when present in the urine is chiefly or altogether eliminated by the glomeruli. The *lymphatics* of the Kidney are divided into two sets, a superficial and deep, the former arise amongst the connective tissue fasciculi of the capsule; the latter accompany the arteries, and are freely distributed between the tubules of the cortical part. They descend in the pyramids beside the *arteriolæ* and *venæ rectæ*, and issue at the hilus, but have many communications also with the superficial set. The *nerves* of the Kidney contain both pale and doubly contoured fibres, and are probably chiefly vaso-motor, though some must be sensory. A few ganglion cells have been found in the tubes.§ To chemical investigation the tissue of the kidney yields Inosit, Taurin, Leucin, Tyrosin, Kreatin, Xanthin, Hypoxanthin, Cystin, and sometimes Urea and Uric Acid.

360. The Kidney is liable to undergo alterations of its normal structure, from a perversion of its ordinary formative processes, which are of a nature very analogous to those occurring in the Liver, though with differences arising out of the peculiarities of its conformation.‖ Several different kinds, as well as degrees, of such alteration, have been described (as it now appears) under the general term "Bright's disease," which has been applied almost indiscriminately to almost every kind of chronic disease of the structure of the Kidney, whether produced by congestion, inflammation, or fatty degeneration, that is attended with the presence of Albumin in the Urine. As has been already

* See Lionel Beale, "Kidney Diseases," &c., 1869, p. 17; Tyson, "American Journal of Medical Sciences," 1869, p. 395; "Lancet," vol. i. 1870, p. 57.

† See Heidenhain, Schultze's "Archiv f. Mic. Anat.," Band x.; v. Wittich, ibid. Band xi. p. 75. ‡ Nüssbaum, Pflüger's "Archiv," Band xvii., 1878, p. 584.

§ Krause, "Allgemeine Anatomie," 1876, p. 245; Loc. cit., p. 75.

‖ For full accounts of the pathological conditions of the Kidneys and of the Urine in "Bright's disease," the reader is referred to the recent works of Drs. Basham, Johnson, Dickinson, and Beale.

stated (§ 140) of the albuminous substances taken up from the alimentary canal, a portion is directly absorbed in the form of albumin, whilst a portion is converted before absorption into peptones. According to Fick,* it is only the albumin which is directly absorbed that is applied to the reparation of the tissues and the formation of the albuminoids of the organism. The peptones, on the other hand, after their entry into the blood, undergo decomposition into urea and non-azotized products, which last may be applied as oxidizable materials to the performance of muscular work and the generation of heat. It is certain that if peptones be injected into the veins of an animal, the whole of the nitrogen they contain appears, in the course of a few hours, in the urine, whilst, if the kidneys have been previously extirpated, the quantity of urea which accumulates in the blood is much greater than after simple extirpation without injection of peptones, or even, after extirpation, with injection of albumin into the veins. Fick specially insists on the great increase of urea that occurs shortly after food has been taken as an evidence that the peptones are rapidly decomposed after absorption. It must be admitted, however, that when large quantities of raw albumin are consumed, a portion is discharged by the kidneys as a foreign substance, and that some kind of assimilating action is probably undergone by all forms of albumin before their entry into the blood;† and it is probably, in part at least, to the want of such assimilation of the newly-absorbed albumin, that we are to attribute the increase of albumin in the urine passed soon after meals, by patients suffering under Bright's disease; something, however, may be due to the simple augmentation of the bulk of the blood, and especially of its solids. But, again, any cause which augments the general blood-pressure, or which produces congestion of the vessels of the kidney, favours the passage of the ordinary albumin of the blood into the urine;‡ and thus we see how albuminous urine may be produced by pregnancy, in which condition the total quantity of blood is increased; by cold, owing to the repulsion of blood from the cutaneous surface to the kidney, by the exciting influence of cantharides or other irritant diuretics, or by any obstruction to the return of blood from the capillary plexus by the renal veins.§

* See Beaunis "Nouveaux Éléments de Physiologie Humaine," 1876, p. 515.

† See Hammond ("Experimental Researches," Philad. 1857, p. 31), who found on restricting himself to a purely albuminous diet, that his urine first contained a great excess of urea, and on the eighth day albumin made its appearance. Bernard also observed its presence in his urine after eating six eggs fasting ("Leçons," 1859, vol. ii. p. 138), and Mr. D'A. Power obtained it after an exclusive diet of eggs for three days.

‡ See Robinson in "Med.-Chir. Transact.," vol. xxvi. p. 51.

§ Magendie, indeed, found that the mere injection of about a pint of water into the veins of a large dog was sufficient to cause the urine quickly to become albuminous, the effect remaining for 10 or 12 hours (Bernard, "Leçons," 1859, vol. ii. p. 139). Overbeck ("Sitzungsbericht: d. k. Akad. d. Wiss. zu Wien," 1863, p. 189) has also made the curious observation that compression of the renal *arteries*, whilst it rapidly diminishes the quantity of urine and of urea secreted, also occasions the discharge of albumin in the urine; though if at the same time a ligature be applied to the ureters, the appearance of albumen is completely prevented. Albuminous urine has been observed in certain forms of heart-disease (Rayer), and after certain lesions of the nervous system, as intra-cranial section of the fifth pair of nerves (Longet, "Physiologie," p. 952), and section of the cerebral peduncles (Schiff); also in scarlet fever, measles, small-pox, erysipelas, pyæmia, typhus, typhoid, rheumatic and malarial fevers, cholera, purpura, scurvy, diabetes, syphilis, certain forms of pneumonia, pregnancy, post-parturient conditions, gout, chronic alcoholism, dyspepsia from excessive eating, and in mollities ossium. See G. Johnson, "British Med. Journal," January 11th, 1873. It has been shown by Brown-Séquard, Schiff, and other experimenters, and especially by Ollivier ("Archives Générales de Méd.," Feb., 1874) that both puncture of the floor of the fourth ventricle, and hæmorrhage into the substance of the hemispheres, is attended with great congestion of the kidneys, and albuminuria, but whether, as Schiff thinks, this is due to paralysis of the vaso-motor nerves, or, as Brown-Séquard thinks, from spasm of the veins,

361. The nature and purposes of the Urinary secretion, and the alterations which it is liable to undergo in various conditions of the system, are much better understood than are those of the Bile: this is owing, in great part, to the two circumstances, that it may be readily collected in a state of purity, and that its ingredients are of such a nature as to be easily and definitely separated from each other by simple chemical means. There can be no doubt that the chief purpose of this excretion is to remove from the system the effete *azotized* matters, which the blood takes up in the course of its circulation, or which may have been produced by changes occurring in itself. This is evident from the large proportion of Nitrogen in the solid matter dissolved in the urine; and from the crystalline form presented by much of this solid matter when separated, a form which indicates that its state of combination is such as to prevent it from conducing to the nutrition of the system. The injurious effects of the retention of the components of the Urinary secretion in the Blood are fully demonstrated by the results of its cessation; whether this be made to take place experimentally (as by tying the renal artery), or be the consequence of a disordered condition of the kidney. The symptoms of *Uræmia* (as this condition has been appropriately termed) are altogether such as indicate the action of a specific poison upon the Nervous system; affecting either the Brain or the Spinal Cord, separately or both together. These effects have been attributed by Frerichs and others* to the conversion of urea in the blood into carbonate of ammonia, and in a case recorded by Spiegelberg not only was the quantity of urea in the urine greatly diminished, but the proportion of this substance in the blood was augmented to three times its normal amount, whilst clear evidence was obtained by Dr. Gscheidlen that the blood contained a considerable excess of ammonia. Experiments on animals in which carbonate of ammonia has been injected into their veins show that conditions analogous to the uræmic state can be established, the animals first becoming restless and then exhibiting both tonic and clonic spasms, and finally passing into a state of deep coma.† Other views again are‡ that the suppression of the urinary secretion prevents the discharge

or of the veins and arteries, leading to engorgement and rupture of the capillaries, cannot at present be stated with certainty.

* See Babington, "Guy's Hosp. Rep.," 1836, p. 360; Owen Rees, "On the Nature and Treatment of Diseases of the Kidney," 1850; Frerichs "Die Brightshe Krankheit," 1851; Spiegelberg, "Archives of Gynæcology," 1870, and Hämpeln, "Dorpat Med. Zeits.," Band iv. 1873, and "Lond. Med. Record," vol. i. 1873, p. 611.

† Voit (Henle and Meissner's "Bericht," 1867, p. 358) is inclined from his experiments to hold that the effects observed in uræmic poisoning are due to the action of the various secondary compounds and alkaline salts proceeding from the disintegration of the albuminous constituents of the body which are retained in the blood in this disease upon the *central* parts of the nervous system, no ammonia being generated except on the intestinal mucous membrane. (See also G. Johnson, "Brit. Med. Journal," vol. i. 1873, p. 192); Mantegazza ("Centralblatt," 1870, p. 576), on the other hand, finding that intravenous injection of urea or of urine produces convulsions both in curarized frogs and even in muscles excised from the body, regards the action as peripheric, and not centric. Traube attributes the symptoms of uræmic poisoning to too great fluidity of the blood, and over-tension of the systemic vessels leading to œdema and anæmia of the brain; but Picot's experiments ("Comptes Rendus," July 6, 1874), in which water was injected at considerable pressure, are opposed to this view. Rosenstein (Virchow's "Archiv," Band lvi. 1872, p. 383), Oppler, and others contend that the symptoms caused by the injection of ammonia differ essentially from those of uræmic poisoning. Urea ingested by the stomach is eliminated unchanged. See Rabuteau in "L'Union Médicale," 1872, No. 142. For an account of the effects of the injection of ammonia into the circulation, see Tibbits, "Med. Times and Gazette," 1872, No. 1166. The whole subject is fully discussed in Bartel's work on 'Diseases of the Kidney' in Ziemssen's "Cyclop.," Amer. Edition, translated by Southey, vol. xv., 1877, p. 109, *et seq.*

‡ Rommeläre, "Journal de Médicine," vol. xliv. and xlv. 1867.

of effete products or the elaboration of albuminoid substance throughout the entire organism, if Nature does not provide some other vicarious mode of supplementing this excretion. Urea is one of the last steps or stages of the metamorphosis of these albuminoid substances, and, when urea accumulates in the blood, it may change the character of this fluid, and consequently the vital (nutritional) processes in various parts of the body. The entire work of transforming the albuminoid substances is arrested, so that we have to deal with the retention in the system, not merely of urea, but also of nitrogenous substances in all the different stages of oxidation through which they pass within the organism.

362. In order to form a correct opinion of the state of the Urinary secretion in morbid conditions of the system, it is desirable to be acquainted with every leading particular regarding its normal character.—Fresh healthy Urine is a perfectly transparent, amber, yellow-coloured liquid, exhaling a peculiar but not disagreeable odour, having a bitterish saline taste, and containing about 1–20th of its weight of solid constituents. The index of refraction for light of fresh morning urine, sp. gr. 1·0206 at 16° C. was found by Valentin to be 1·3395, but it may rise to 1·3443.* It is less when the urine contains albumin, higher when it contains sugar. The only morphological elements which it normally contains are pavement epithelium cells and mucous corpuscles from the lining of the urinary passages; which, however, are present in healthy urine to only a very small amount. But in certain morbid states of the urine, minute cylindrical bodies are seen in greater or less abundance, which are obviously derived from the tubuli uriniferi; these are sometimes composed almost exclusively of the epithelial lining of the tubes, of which the cells remain adherent to each other, notwithstanding their detachment from the basement membrane beneath; whilst sometimes they are fibrinous moulds of the interior of the tubes, formed by exudation of granular plastic material, and containing blood or pus-corpuscles; whilst in other instances, again, they are perfectly transparent, or hyaline, and are then believed by Dr. Basham to correspond to the viscid mucous exudations poured out from all inflamed mucous surfaces. The first of these forms occurs chiefly in desquamative irritation of the kidneys; the second, as a consequence of acute inflammation, and the last, in the advanced stages of "Bright's disease," as well as in the gouty and atrophic kidney.†—In all natural conditions of the Human system (even when a vegetable diet is used, though it may then become neutral) the urine possesses a well-marked acid reaction. When it is left to itself for some time, slight nebulæ, consisting of mucus, are formed in it; and these gradually fall to the bottom. Soon afterwards an unpleasant odour is developed; instead of an acid, an alkaline reaction is presented, in consequence of the decomposition of the urea into carbonate of ammonia; and a precipitation of earthy phosphates then takes place. A turbidity may be produced, however, by the precipitation of urates of soda and ammonia, on the simple cooling of the urine, without any such departure from its normal composition as would probably constitute disease, but under some of the conditions hereafter to be specified. But if the urine be turbid when it has first passed from the body, and has a temperature of 98° or 100°, it must be considered as abnormal.

363. *Quantity.*—Dr. Parkes,‡ who has collected the averages of many

* Pflüger's "Archiv," 1879, p. 85, Band xix.

‡ "On the Urine," p. 5.

different observers, states that 52½ fluid ounces may be considered to represent the mean quantity of urine discharged in 24 hours by healthy male adults between 20 and 40 years of age.* The extremes given by different experimenters are, 35 ounces (Prout), and 81 ounces (Böcker). Almost every intervening number between these two remarkably different quantities has been stated by one observer or another to be the usual average. Great differences therefore exist, even in healthy adults; and the amount will vary with the quantity of fluid ingested, the external temperature and consequent activity of the cutaneous transpiration, the nature and quality of the food, the temperament of the body, and perhaps even with national peculiarities. Dr. Ed. Smith, from daily experiments made throughout the year, has shown that during a cold summer (half-year from May to October) the average quantity was somewhat more, whilst during a hot summer it was somewhat less than during the winter six months. With alcohol given to prisoners there was an average decrease of 20 ounces per day for three days, the quantity of water drunk being unchanged. With a day of rest the quantity was less than on days of labour, and there was more on treadwheel days, notwithstanding that the quantity of water drunk was the same, and there was more perspiration with the hard labour. Women secrete somewhat more urine than men,† and children nearly twice as much in proportion to the weight of the body. Some time, however, usually elapses after birth before the kidneys begin to discharge their function with activity, the urine up to the third day being usually scanty, albuminous, destitute of urea, and containing but a small proportion of solid ingredients. In infants from eight to eighty days of age the quantity of urine discharged varies from 250 to 410 cub. cent. ($\frac{1}{2}$ to $\frac{3}{4}$ of a pint) per diem, and is almost always acid.‡

364. The secretion of urine is considered to be essentially the product of two factors, one of which is the difference of pressure between the circulating blood and the excreted urine, whilst the other is the amount of urinary material which the blood contains.§ But it must also be connected with the activity of the cells lining the renal tubuli, whilst the influence of the nervous system and the composition of the blood probably form other factors. The influence of the blood-pressure is shown by the circumstance that when this is low the secretion is diminished; and if the pressure fall below 40 mm. Hg it is entirely arrested: on the contrary, when the blood-pressure is high, the secretion is augmented. The ordinary amount may be estimated at 120–140 mm. Hg, whilst the pressure of the urine in the ureters varies from 10–40 mm. Hg. That the quantity of the secretion is not exclusively dependent upon the blood-pressure is shown by the fact‖ that injection of a large quantity of distilled water into the veins of an animal promptly arrests the secretion. Moreover, if solution of sugar be injected into the veins, polyuria results without increase of blood-pressure; whilst the injection of a solution of gum augments the blood-pressure, but greatly checks or altogether arrests the secretion of urine. It may be observed that the pressure of the blood in the renal vessels is not always identical with that of the system generally, since, although it must necessarily fall when the aortic pressure falls, it may be reduced considerably below that in the systemic arteries generally, by any

* This number agrees very exactly with the careful experiments of Dr. Ed. Smith and Kaupp, "Archiv. f. Phys. Heilk.," Band xiv. † Donders, "Physiologie," p. 485.

‖ R. Moutard-Martin and Ch. Richet, "Rev. Scient.," 1880, pp. 715 and 763.

cause leading to contraction of the renal arteries. In accordance with this, diminution or arrest of the secretion occurs both when the general blood-pressure has been diminished by bleeding, and also when the local tension has been reduced by compression of the renal arteries. In one of the experiments recorded by Goll, the urine being discharged by the ureters at the rate of 30 or 40 drops per minute, the animal was bled, when the flow immediately diminished to 12 drops per minute, but upon transfusing into its veins some blood taken from another animal it rapidly rose to 188 drops per minute. The same effect may be produced by acting on the renal circulation through the nervous system, as by irritating the pneumogastrics, which depresses the action of the heart, or by section of the spinal cord (Ustimowitsch), or of the sympathetic* at the lower part of the neck. Augmentation of the secretion, on the other hand, occurs when the pressure of the blood is either increased generally, as during digestion (Bernard), or locally in the renal capillaries, by ligature of the renal veins or of some of the larger systemic arteries, as the crural and axillary, or by the action of cold on the cutaneous capillaries. It may also be induced by division of the renal nerves, which, paralysing the vaso-motor system, allows the arteries to dilate and leads to a freer current of blood through the kidney. Vulpian found that section of the splanchnics is followed by similar, but less marked, augmentation, because such section also paralyses the vaso-motor system of the abdominal viscera generally, and, though allowing a fuller current of blood through the kidneys, lowers the blood-pressure as a whole.† Increased secretion of urine follows division of the pneumogastrics and puncture of the floor of the fourth ventricle. Hydruria is occasioned by mental emotions, fear being the one which most powerfully stimulates the kidneys to act, and the effect is observable both in animals and in man. It may act like cold by contracting the cutaneous arteries and producing congestion of the abdominal viscera generally, since diarrhœa is also frequently induced. The large flow of pale urine in Hysteria, as the attack is passing off, is well known; and occasionally this occurs as a critical discharge in some febrile affections. The importance of the other factor on which the secretion of urine depends is sufficiently demonstrated by the results of an experiment suggested by Ustimowitsch, who found that when the secretion of urine had been arrested by section of the spinal cord in the lower part of the neck, and common salt or urea was injected into the veins, secretion recommenced notwithstanding the great diminution of the blood-pressure consequent on the section, and with each additional gramme of sodium chloride injected, a very definite quantity (15–16 grammes) of water was discharged. So also when a large quantity of fluid has been absorbed within a short space of time, it is rapidly discharged by the kidneys, nearly all having escaped at the expiration of 2½ hours after the last portions have been taken.‡ The two kidneys do not secrete similar fluid at the same time, but one eliminates a more watery, the other a more saline fluid, alternately.—Curare administered in poisonous doses arrests or greatly diminishes the amount of urine secreted; Digitalis, probably, in part by augmenting arterial tension,§ and the inhalation of carbonic oxide gas increases it. It is a matter of common observation that injuries of the spinal cord are followed by changes in the constitution of the urine, which becomes ammoniacal and precipitates phosphates; but it appears

* Peyrani, "Comptes Rendus," t. lxx. p. 1300.

† Küss thinks that the serum of the blood naturally filters through the capillaries of the glomeruli, and that it is the function of the cells of the contorted portion of the tubules to reabsorb the albumin. ‡ Thudichum, "On the Pathology of the Urine," p. 26, 1858.

§ See Brunton and Power, "Centralblatt f. d. Med. Wiss." 1874, p. 497.

to be doubtful whether these changes are not the result of disordered secretion from the walls of the urinary bladder, the urine being secreted normally, but undergoing in its course through the urinary passages a kind of fermentation, which induces decomposition of the urea and the formation of carbonate of ammonia.*

365. The *Specific Gravity* comes to be a very important character in various morbid conditions of the urine; and it is therefore desirable to estimate it correctly. This also is, of course, subject to many causes of variation; since, when the same amount of solid matter is dissolved in a larger or smaller quantity of water, the specific gravity will be proportionably lower or higher; or, the quantity of water remaining the same, an increase or diminution in the amount of solid matter will raise or lower the specific gravity. It has been commonly supposed that the amount of solid matters in the urine bears such a constant ratio to its specific gravity, that the former may be approximately deduced from the latter; this, however, is now ascertained to be by no means the case.† Still, the determination of the specific gravity is of sufficient importance for diagnostic purposes to make it desirable to possess an average standard, as nearly approaching to accuracy as circumstances will permit. The average, according to Dr. Prout, in a healthy person, taking the whole year round, is about 1020; the standard rising in summer (on account of the greater discharge of fluid by perspiration) to 1025, and being lowered in winter to 1015. Simon, however, states the average specific gravity at no more than 1012. Dr. Roberts‡ observed the specific gravity of his own urine, while in a healthy state, to vary from 1001 to 1036. The first urine passed by infants has a specific gravity of 1010, and often contains columnar epithelium and remains of cells.§ In infants of a few weeks old the specific gravity varies from 1005–1007. That the specific gravity does not bear any constant relation to the quantity discharged has been shown by Dr. Hammond, who noticed that, although the afternoon and evening urine was most abundant, its specific gravity was very high, in consequence of its containing a large proportion of solid ingredients. The specific gravity of the urine probably depends mainly, in each individual case, upon the amount of azotized solids and of aqueous fluids habitually ingested, allowing for the portion of the latter that is dissipated by cutaneous exhalation; and it will also vary with the period that has elapsed since the last introduction of liquid into the stomach.

366. The amount of *solid matter* in 1000 parts of urine may vary from 20 to 70 parts; and hence the various recorded analyses of this liquid present very wide diversities in the proportion of its solid constituents.‖ The following

* Schiff (Lezioni, 1873, p. 329) has pointed out that injuries of the medulla oblongata cause hyperæmia of the kidneys, closely resembling the second stage of Bright's disease, which he attributes to paralysis of the vaso-motor nerves, whilst Brown-Séquard ("Comptes Rendus de la Société de Biologie," 1871, t. iii. p. 101, and "Lancet," 1871, vol. i. p. 6) attributes the congestion and hæmorrhages seen in the kidneys and other abdominal organs to contraction of the veins, or to simultaneous contraction of both arteries and veins. Ollivier (Archives de Médecine," Feb. 1874) gives various chemical observations showing the rapidity with which albumin appears in the urine after an attack of apoplexy.

† See Lehmann's "Physiological Chemistry" (Cavendish Society), vol. ii. p. 436.

§ Pollack, Loc. cit., and Martin and Ruge, "Centralblatt f. d. Med. Wiss.," 1875, p. 387.

‖ It is remarked by Lehmann (Op. cit., p. 447), that the urine of the French is poorest in solid constituents, especially in urea and uric acid, and that of the English the richest, that of the Germans being intermediate between the two; the ratio in each nation being in conformity with the proportion of animal food entering into its ordinary diet. These discrepancies, however, being chiefly due to the fluctuating amount of water, become very much

Table* will show the usual constituents of healthy urine, and the quantities excreted in 24 hours:—

Urinary Constituents.	Average quantity excreted in 24 hours, in grains.	Average quantity excreted for each 1 lb. avoird. of body-weight (estimating this at 150 lbs.), per diem, in grains.
Urea	512	3·5
Uric Acid	8·5	0·057
Allantoin	A trace.	—
Hippuric Acid	15	0·1
Kreatinin	15	0·1
Sugar		
Xanthin		
Acids: Paraphanic, Kryptophanic†, Phenylic, Taurylic, Damaluric, Damolic, Crystalline fatty acid, possibly Palmitic (Shunck), Oxaluric, Oxalic	Traces.	—
Pigment, especially Indican		
Mucus	7	—
Inorganic Salts (varying greatly in their relative proportions according to the nature of the food, and composed of)	140 to 380	0·933 to 2·53
Sulphuric Acid	17·34 to 41·14	0·115 to 0·27
Phosphoric Acid	31 to 79	0·207 to 0·526
Nitric Acid	A trace.	—
Silicic Acid	Traces.	—
Chlorine	51·87 to 173·2	0·345 to 1·154
Potassium	26·36 to 107·7	0·175 to 0·718
Sodium	79·75 to 171·0	0·531 to 1·14
Calcium	2·33 to 6·36	0·015 to 0·042
Ammonium	—	—
Ma4nesium	2·53 to 4·21	0·016 to 0·028
Iron‡	A trace.	—

less (as Simon pointed out) when we calculate the proportion which each principal component bears to 100 of solid residue; as is shown in the following Table:—

	Berzelius.	Lehmann.	Simon.	Marchand.
Urea	45·10	49·68	33·80	48·91
Uric acid	1·50	1·61	1·40	1·59
Extractive matter, Ammonia-salts, and Sodium Chloride	36·30	28·95	42·60	32·49
Alkaline Sulphates	10·30	11·58	8·14	10·18
Alkaline Phosphates	6·88	5·96	6·50	4·57
Phosphates of Lime and Magnesia	1·50	1·97	1·59	1·81

* Chiefly drawn up from the works of Parkes "On the Urine," 1860, Lond.; Thudichum, "On the Pathology of the Urine," 1858, Lond.; and Neubauer and Vogel, "On the Urine," Lond. 1863, New Sydenham Society's Translation; to which treatises the reader desirous of further information is referred.

† The presence of Paraphanic and Kryptophanic Acids is given on the authority of Dr. Thudichum ("Centralblatt," 1870, Nos. 13 and 14); his statements have been called in question by Pircher, "Centralblatt," 1871, p. 322, but he has reiterated them in Pflüger's "Archiv," Band xv. 1877, p. 466. He also admits the presence of Acetic and Formic Acids in the Urine, ibid. p. 15.

‡ See Thudichum, Op. cit.

It is difficult, if not impossible, to determine the exact mode in which the acids are distributed amongst the bases, but the Chlorides and Phosphates seem to be eliminated in the following proportions:—

	Grains in 24 hours.	
Sodium Chloride	about 250	
Ammonium Chloride	„ 35	
Magnesium Phosphate	„ 5	} Lehmann and
Calcic Phosphate	„ 10	} Kletzinsky.

The relation between the two last is reversed by Neubauer.

The urine contains, in addition, free carbonic acid, oxygen, and nitrogen gases; together with a certain and not inconsiderable quantity of extractive matters, consisting of substances whose nature has not been accurately determined, as in the case of those containing sulphur and phosphorus, the substance termed Oxide of Omichmyl by Scharling (which is apparently of a resinous nature), and others. The aggregate amount of the extractives is estimated by Dr. Parkes at 154 grains per diem, and constitutes an important field for future investigations. It will thus be seen that the total quantity of solid material eliminated by the kidneys does not fall far short of 900 grains in the 24 hours for a healthy adult man weighing 150 lbs., the proportion of organic compounds being about 550 grains, and of inorganic about 300 grains. The new-born child yields in 24 hours per pound of body weight less urea and chlorides, but it eliminates more phosphates and more water.*—Under the head of constituents not constantly, or not certainly, present, or perhaps present only in disease,† may be enumerated albumin, peptone, kreatin, xanthin, sarkin, grape-sugar, inosite, diastatic and proteolytic ferments,‡ glycin in combination with benzoic acid, forming hippuric acid,§ lactic and oxalic acids, fatty substances, blood and biliary colouring matters, salts of the biliary acids, allantoin, leucin, and tyrosin, succinic acid, cystin, inosite, taurin, hæmatin, pus, spermatozoa, carbonate of ammonia, phosphate of ammonia and magnesia, and sulphuretted hydrogen,‖ besides various substances consumed as food and eliminated by the kidneys, as the colouring and odorous matters of various vegetables and certain metals. The acid reaction of the urine depends essentially on the presence of the acid phosphate of soda; and the curious observation has recently been made that in dialysing the neutral phosphate of soda, the acid phosphate appears on the other side of the septum.

367. The most important of the organic constituents of the Urine is that which, from its being the principal source of the characteristic properties of the secretion, is termed *urea*.¶ Its chemical relations are stated to be best explained upon the hypothesis that it is the biamide of carbonic acid.** It contains 46·6 per cent. of its weight of Nitrogen. This substance exists preformed in the blood in the proportion of from 2 parts (in renal venous) to 4 parts (in renal arterial blood) in 10,000. It possesses the power of dialyzing through animal membranes with remarkable facility, almost equalling carbonate of potash in this

¶ Urea, $CO(NH_2)_2$, contains 46·7 per cent. of nitrogen, and is isomeric with ammonium cyanate, $CNNH_4O = \left.\begin{matrix} C'' \\ H_2 \\ H_2 \end{matrix}\right\} N_2$, and with carbamide, $\left.\begin{matrix} O'' \\ H_2 \\ H_2 \end{matrix}\right\} N_2 + CO_2$.

** Miller's "Chemistry," vol. iii. p. 615.

respect.* It is eliminated by the cells of the renal tubuli.† The absolute quantity of urea eliminated in 24 hours, varies with age, season, weight of body, food, and occupation, and has been made a subject of examination by various chemists. The subjoined Table‡ gives the results of some of the more recent analyses; and from the examination of such tables we may draw the conclusions, that the average quantity of urea discharged by a man of good bodily health, on full animal diet, is about 500 grains per diem; and that children of from 3 to 7 years of age excrete, proportionately to their weight, about double the quantity of urea per diem excreted by men in adult life, the quantity still further diminishing in old age. The minimum amount excreted by an adult whilst fasting and at rest is about 2 grains per 1 lb. of body-weight. In infants at the breast Pollack (loc. cit.) found the quantity to vary from 15 to 30 grains per diem.

Season.—Dr. Ed. Smith,§ in the course of the year, found that the daily quantity (in himself) varied from 219 to upwards of 700 grains, the average upon the whole being 519 grains. The proportion to each 1 lb. of body-weight was, on the whole average, 2·76 grains. But in experiments in prison, either with or without hard labour, the proportion varied from 3·72 to 5·82 grains to each 1 lb. of body-weight; so that he is of opinion that the relative proportion is of no scientific value. There was increase with diminished temperature and with increased atmospheric pressure, and hence variations in the relations of these two agencies varied the results. The increase in the elimination of urea with cold was often deferred until the following day. The period of elimination is not that of production, and whatever increases elimination of urine increases that of urea also. G. Schleich‖ found that on exposure of the body to a water-bath, at a temperature of 100°—108° F. for about an hour, the daily amount of urea eliminated was always increased, the augmentation sometimes lasting to the third day.

Period of the Day.—The greatest hourly elimination of urea, in Dr. Smith's

According to Hofmann the healthy adult man eliminates in 24 hours from 22-43 grammes of urea = 0·37–0·6 per kilo of his body weight, the average being 34 grammes = 0·5 per kilo. The healthy adult woman from 16–28 grammes = 0·36—0·43 per kilo; on the average 25 grammes = 0·4 per kilo ("Zoochemie," 1879, p. 404).

§ "Proceedings of the Royal Society for May 30, 1861," and a private communication.
‖ "Archiv f. Exper. Pathol.," Band iv. p. 82.

experiments, occurred after the breakfast and tea meals; whilst it was least during the hours of the night and early morning. Ranke found that it steadily diminished from the morning to the evening.

Sex.—According to Dr. Parkes, the quantity of urea excreted every 24 hours, for 1 lb. of body-weight is, for men, about 3½ grains; for women, about 3 grains. During menstruation, according to Beigel, the excretion of urea diminishes, but subsequently it is increased.

Food.—Variations in the quantity and quality of the food occasion great differences in the proportion of the urea. The Table below* gives the results in grains of some of the best observers.

The immense amount of urea discharged upon a highly albuminous diet is worthy of particular notice. The quantity of urea always increases after food, attaining its maximum usually about the third or fourth hour, and this would correspond with the period when digestion and absorption being completed the interstitial changes in the cells and tissues throughout the body are being performed with the greatest activity. When an animal is fed on fat and water exclusively, or on starch and fat, with a very small admixture of albuminous compounds, or on sugar, the excretion of urea falls even below the proportion found in absolute starvation,† apparently because when no food, or an inadequate quantity of flesh-food, is given, the animal consumes some of its own flesh in order to maintain its temperature, and thus more Nitrogen is eliminated than when fat is supplied; for this, by combining with the Oxygen, keeps up the temperature, and spares the tissues of the animal. It is certain that nearly the whole of the Nitrogen consumed as food is eliminated by the urine in the form of urea. Thus, in an experiment made by Professor Parkes,‡ extending over sixteen days, two men who consumed in that period 313·76 grammes of Nitrogen in their food, discharged by the urine in the same time 303·66 and 307·257 grammes of urea respectively, the difference being made up by the fæces and other excretions. Every grain of urea may be regarded as proceeding from the disintegration of 3 grains of Protein, and represents the amount of work performed in raising 1·4 ton through one foot. So that on the supposition that 501·28 grains are eliminated in the day, the amount of work performed would amount to 218,786 kilogrammeters, or 704 foot tons (Haughton). Genth§ has shown that an increase in the quantity of water drank is followed by a marked increase in the quantity of urea eliminated, and this especially if the water be taken, not between, but at, meat times. Certain substances consumed with the food increase the quantity of urea excreted; amongst these are Urea itself and Uric Acid, common Salt (Voit), Phosphoric Acid (Böcker), Glycin, Guanin, Theobromine, Cubebs,

and Cantharides.* On the other hand, it is diminished by Digitalis, Arsenic, Turpentine, and Alcohol.

Exertion.—The influence of muscular exertion on the excretion of Urea is a subject to which great attention has been directed during the last few years, as being likely to afford some insight into the source of muscular energy, and to show whether the force exerted by muscle is derived from the disintegration and oxidation of its own proper substance, or whether it proceeds from the oxidation of certain constituents, and especially of the hydrocarbonaceous constituents of the blood, the heat derived from which the muscular tissue is capable of converting into mechanical force. In the former case we should naturally expect that the nitrogenous products of the disintegrated muscular tissue would appear in the urine, in the latter we should anticipate an increase in the amount of carbonic acid and water eliminated from the body, without material increase in the excretion of Nitrogen by the urine. The facts of the case, as will be seen, are opposed to the view that the tissue of the muscle is materially disintegrated during exercise, and in favour of the view that the energy is derived from the oxidation of hydrocarbonaceous compounds. The experiments of Dr. Ed. Smith were amongst the first to show that muscular exercise was not attended with any notable increase in the amount of Urea eliminated. He found that with violent labour, as that of the treadwheel, there was only an increase of 19 grains daily over that of light labour. On Sunday there was an increase with increase of food; but in prisoners without variation of food, with spare systems, and with increase in the fæces, there was a decrease. Similar results were obtained by Voit,† who, in consequence of the very small differences that occurred in the quantities of urea eliminated in fasting animals (Dogs) with and without work, believed that such slight increase of urea as really occurs after severe labour, is due to increased thirst and ingestion of water, together with increased rapidity of the movements of the heart and lungs. Lehmann's‡ experiments also showed that no increase of urea took place in those engaged in active exercise. In 1866 an important experiment bearing on this point was made by MM. Fick and Wislicenus.§ These observers investigated the variations occurring in the amount of Nitrogen eliminated by the urine during the ascent of the Faulhorn, one of the peaks of the Swiss Alps, and about 6500 feet in height. They took no albuminous food for seventeen hours previously, nor during the ascent, which occupied eight hours, nor for six hours after, their diet consisting of biscuits of starch, fat, and sugar. The examination of the urine gave the following results:—

	The average quantity of Nitrogen excreted per hour was, by	
	Fick.	Wislicenus.
1. Urine of the night previous to the ascent—a period of 12 hours	0·63 gramme.	0·61 gramme.
2. Urine of the period of ascent—8 hours and 10 minutes . .	0·41 „	0·39 „
3. Urine excreted for 6 hours after the ascent	0.40 „	0·40 „
4. Urine of the night following the ascent, after a good meal had been taken—10½ hours	0·45 „	0·51 „

Here there was evidently a decrease in the excretion of nitrogen during and after exercise, but it must be remembered that no nitrogenous food was consumed. Very similar results were obtained by Professor Haughton,‖ who found that with about five miles of daily walk the amount of urea eliminated

* v. Gorup-Besanez, "Physiolog. Chem.," p. 540, 1862.

was 501·28 grains per diem, whilst when the exercise was increased to 20·74 miles of horizontal walk for five consecutive days, the amount of urea was 501·16 grains; actually less than the previous average. Two still more complete series of experiments have been conducted by Professor Parkes* on two soldiers, in the first series of which he investigated the elimination of nitrogen by the kidneys and intestines, during rest and exercise, on a diet without nitrogen; whilst in the second series the men were placed on a regulated diet of nitrogen. In the first series of experiments the men were kept for a first period of six days on ordinary diet and occupation, in order to determine the conditions present in perfect health, and to serve as a ground of comparison. Then for a second period of two days' duration the men were kept on a non-nitrogenous diet and remained at rest. Under these circumstances the urea fell from 35 grammes (which was about the usual daily amount with ordinary diet), to 16·7 in one man, and in the other from 26 to 15 grammes, or in both to about one-half its ordinary amount. During the third period of four days, the men returned to their usual diet and occupation, by which time they were considered to have regained their ordinary condition, and the quantity of urea excreted rose to its ordinary amount. During the fourth period of two days, the men were again placed on non-nitrogenous diet, but on this occasion were made to take severe exercise; walking on the first day 23·76 miles, and on the second day 32·78 miles. It was found that during the first thirty-six hours there was a decrease; but in the last twelve, or rest-hours of the forty-eight hours, an increase in the amount of urea; and that, on the whole, the effect of the exertion of walking fifty-six miles on a non-nitrogenous diet was a total increase of only 1·589 gramme of nitrogen in one man, and in the other of only 0·223 gramme in the forty-eight hours. In the fifth period the men once more returned to their ordinary diet and occupation for four days, in which a considerable increase of nitrogen over the average amount was observed; which however is referred by Dr. Parkes, not to the elimination of the products of destroyed muscle during the work-period, but to an excess of nitrogenous food consumed in the four days following the exercise. In the second series of experiments two men were kept on the same nitrogenized diet for sixteen days. For four days they were kept at their ordinary employment; during two days rested; returned to ordinary work for four days; took very active exercise for two days, walking twenty-four and thirty-five miles, and were then for four days more on ordinary occupation. The changes that took place in the urea were almost identical with those in the total nitrogen eliminated, and so nearly equal to that in amount, that (allowance being made for what passed by the bowels) it was certain none passed off, either during rest or exercise, by the skin or lungs. The results were, that in the first period the amount of urea was almost precisely the same in the two men. In the rest-period it increased nearly two grammes daily in each man, fell during the third period to the former average, decreased greatly during the first thirty-six hours of the exercise-period as compared with the rest-period, and increased in the last twelve hours; in the last or after-work period it also increased, though in a less proportion than the total nitrogen. The first series of these experiments undoubtedly corroborate the statement of Fick and Wislicenus, that on a non-nitrogenous diet exercise produces no notable increase in the nitrogen of the urine; although, when the subsequent period is also considered, it does produce a slight increase. The second series showed that, with an unchanged amount of nitrogen ingested, so far from there being any increase, there was an actual diminution in the amount of

* "Proceed. Roy. Soc.," Nos. 89, 94, 1867.

urea eliminated both during ordinary and during severe exercise, as compared with rest. There was, on the other hand, an excess, not great but long-continued, in nitrogenous excretion after exercise; and there was a retention of the nitrogen in the system when it was again supplied after both rest and exercise, and greatest in the latter case, showing that it is needed in the system, and that an insufficient supply at one time must be subsequently made up. In some recent experiments by Weigelin,* it appeared that if, after two hours of strenuous muscular exercise, the amount of urea eliminated during the succeeding two hours were determined, an increase of as much as 50 per cent. on the ordinary average was sometimes observed. Persistent muscular effort (tetanus) was found to produce more urea than the alternate contraction and elongation of muscle. In 1870 and 1871 a very important and complete series of observations on the effects of protracted and severe muscular exercise upon the excretion of nitrogen were made by Dr. Austin Flint, aided by several other physiologists.† The subject of the experiment was Mr. Weston, who in the first instance walked 100 miles in twenty-one hours and thirty-nine minutes, and subsequently attempted to walk 400 miles in five consecutive days; which, however, he failed to accomplish. Dr. Flint made a careful examination of the urine for five days preceding the walk, for the five days of the walk, and for five days after the walk. Mr. Weston was thirty-one years of age, and his weight was about 120 lbs. He smoked in moderation, and was an almost total abstainer from alcoholic fluids. On the first day of the walk he made 80 miles, on the second 48, on the third 92, on the fourth 50, and on the fifth 40. The failure occurred on the fourth day, from vertigo, partly induced by want of sleep. During the five days of the walk Mr. Weston consumed in all 1173·80 grains of nitrogen in his food, and eliminated 1807·60 grains of nitrogen in the urine and fæces. This leaves 633·80 grains of nitrogen over and above the nitrogen of the food, which must be attributed to the waste of the tissues, and probably almost exclusively to the waste of the muscular tissue. Lean meat, as has already been shown, contains about three per cent. of nitrogen (§ 337). The loss of 633·80 grains of nitrogen would then represent a loss of 21,127 grains, or 3·018 lbs. of muscular tissue. The actual loss of weight was 3·450 lbs., which allows 0·43 lb. loss unaccounted for, which might be fat or water. It would hence appear that there was a distinct consumption of muscular substance during the immense exertion of the period of five days' walking. In two days after the walk, the weight of the body had been made up to within four ounces of the normal weight. Schultzen and Nencki‡ have shown that Leucin and Glycocol administered to dogs greatly increase the amount of urea eliminated. Tyrosin causes no increase, but is expelled unaltered. Cerebral activity§ and sexual excitement‖ augment the quantity of urea.

Frequency of Micturition.—Kaupp¶ has shown that with increased frequency of micturition there is an increase in the quantity both of urine and of urea discharged in twenty-four hours.

Disease.—The amount of urea eliminated increases in the early stages

* Reichert's "Archiv," 1868, p. 207.

† See "New York Medical Journal," June, 1871, pp. 609–697. The subject has been again discussed by Dr. Pavy, "Lancet," 1876; and by Dr. Austin Flint in Humphry's "Journ. of Anat. and Phys.," 1878, vol. xii. p. 91. Dr. Flint endeavours to prove that the source of muscular power is to be sought in the destruction of muscular substance.

‖ Haughton, loc. cit., found the ordinary quantity of urea to be in the sheep 256 grains per diem, but in the ram during the rutting season 1493 grains per diem.

¶ "Archiv f. Phys. Heilk.," 1856.

of nearly all acute diseases,—meningitis, pneumonia, typhus, &c.,—indicating the rapid disintegration of the nitrogenous tissues and constituents of the blood, and coinciding with the period during which increased heat of skin is usually complained of. This, though not more than 4° or 5° Fahr. above the average, represents (from Newton's law of cooling) an increase of one-eighth of the total amount of heat produced—an amount equivalent to the force required to raise the body through one mile of vertical height per diem,* and furnishing an adequate explanation of the extreme exhaustion experienced by the sufferers at this period. Vogel and Warnecke found that in a case of typhoid fever no less that 1065½ grains of urea were excreted daily, or more than double the usual average, and in a case of pyæmia the extraordinary quantity of 1235½ grains. Now as every four grains of urea excreted correspond to five tons lifted through one foot, it is obvious that an enormous amount of force is spent in these diseases, fully accounting for the extraordinary debility induced in such patients. When the fever is over, the quantity of urea falls below the normal amount, in spite of the augmented quantity of nitrogenous food ingested, which is doubtless appropriated to the repair of the wasted tissues, and it then, after perfect recovery, returns to the normal standard. During convalescence it gradually subsides, and may even fall below the normal amount. The proportion appears to be remarkably diminished in some forms of hepatic disease. Thus Frerichs,† in a case of acute atrophy of the liver, found no trace of urea in the urine, but in its place leucin and tyrosin. In another case, recorded by Vogel, of cancer of the liver, scarcely one-fourth of the normal quantity of urea was found in the urine; and Heller has shown that the proportion of urea is diminished in chronic nervous affections, and in anæmia, however produced.‡

368. Next in importance to urea among the organic products of the metamorphosis of the azotized constituents of the tissues or of the blood, but ordinarily bearing a very small proportion to it (1 : 45 or 50) in quantity, is *Uric Acid* ($C_5H_4N_4O_3$). This compound contains 33 per cent. of nitrogen. It probably exists in the urine, partly in the free state, and partly combined or conjugated with the alkaline phosphates.§ The variations in the daily quantity eliminated are considerable; and, according to Ranke, whilst in great measure independent of differences in age, sex, height, weight, or temperature, stand in close relation with the ingestion of food, diminishing to a minimum of 3·7 grains with abstinence, and rising to a maximum of 32·5 grains on a full meat diet. Professor Haughton found the average quantity elimininated by those consuming animal food to be 4·55 grains per diem, whilst vegetarians discharged only 1·48 grains. Pollack‖ found that the quantity was relatively large in infants at the breast, varying from 1·5 to 3 grains per diem. It is diminished after the use of alcohol (Hammond), and after the administration of quinine (Ranke), and is totally absent when large draughts of water have been taken (Genth). It is increased after the free use of tobacco (Hammond), and after the consumption of certain substances introduced into the food, as glycin and urea, but no influence is exerted on its quantity by mental activity or repose (Byasson). The effects of muscular exercise were found by Austin Flint¶ to cause slight increase, the quantity passed by Mr. Weston in his long walk of 317½ miles in five days, being at the rate of three grains per diem, whilst during the five days previous to the walk it was 2·26 grains, but the quantity varied considerably on each day, without it being possible

to connect this variation with the composition of the food or the amount of the exercise taken. A marked increase has been observed in intermittent fevers, in leucæmia, in peritonitis, phlebitis, and some chronic renal and spinal affections. Uric acid is found in the spleen-pulp in considerable quantities, and also in the lungs, liver, pancreas, and brain; in the juice of muscles, and in small quantities in the blood (Garrod) in the form of an acid urate of soda or ammonia.* It seems, therefore, to be very generally present where active interstitial changes are taking place. The *precipitation* of uric acid (usually in combination with potash, soda, and ammonia, and perhaps sometimes with lime), which frequently takes place on the cooling of the urine, must not be regarded as indicative of the presence of an unusual amount of this substance; since it may depend upon other conditions. It seems to have been clearly proved by Dr. Bence Jones,† that there is no relation whatever between the *acidity* of the urine, and the *absolute amount* of uric acid which it may contain; for in the urine which is most acid, and which deposits the largest uric-acid sediment, very little uric acid may really exist; whilst that which contains most uric acid may hold it in perfect solution, and may have but a feeble acid reaction. The main cause of the deposit of uric acid sediments, is doubtless the presence of some other acid; for the addition of any acid to healthy urine passed soon after food, is always sufficient to produce it. But the deposit takes place less readily if the temperature of the fluid be high, since the solvent power of the acid phosphate of soda is then more strongly exerted; so, on the other hand, a deposit often takes place in urine which would not otherwise exhibit it, through an unusual reduction in its temperature, as by exposure to the cold air of a sleeping-room in the winter. Again, the deposit of uric-acid sediment is favoured by concentration of the liquid, which thus augments the proportion of the urate to the water, and at the same time intensifies the acid reaction; and thus urine whose constituents are otherwise normal, may throw down a copious deposit of this kind, merely from deficiency of water; whilst an unusual amount of uric acid may be really present without being deposited—the urine, too, exhibiting its ordinary acidity—if the proportion of water be large. Thus the uric-acid sediment may be regarded as dependent upon three concurrent conditions:—(1) Decrease of temperature; (2) Increased proportion of uric-acid compound to the water, positively or relatively; (3) Increased acidity of the urine. Sometimes one condition is most influential, sometimes another; but they are all usually concerned in some degree.—There are many diseases, especially those of a febrile nature, in which the presence of an *excess* of uric acid is a very marked symptom; there is often, at the same time, a reduction in the proportion of urea; and thus it would seem that, with perhaps an augmented tendency to disintegration of the tissues, there is an incapacity for the performance of that higher process of oxidation, which is requisite for the genesis of urea; so that a larger proportion of the products of the 'waste' passes off in the state of uric acid, as in animals whose respiration is feeble.

The proportion of *Hippuric Acid* ($C_9H_9NO_3$) present in the urine appears to be in great measure dependent upon the nature of the food and upon the amount of exercise. According to the researches of Weissmann and Thudichum, it amounts to between 30 and 40 grains per diem on a mixed diet. On a purely animal diet, it falls to about 12 grains per diem; whilst it rises considerably when vegetables alone are consumed; and its origin has been

* Thudichum, "Pathology of the Urine," p. 97.

† See his 'Contributions to the Chemistry of the Urine,' in "Philos. Trans.," 1849.

attributed by Sheppard and Meissner* to the conversion at the kidney of a substance existing in the cuticle of plants nearly allied to Kinic acid. As might be anticipated, therefore, a large quantity of this acid is constantly present in the urine of Herbivora, but only traces exist in that of Carnivora. Both Mack and Roussin found that horses at rest pass much urea and little Hippuric acid: but when at work, the quantity of Hippuric acid equalled or exceeded that of urea, the absolute quantity of the latter undergoing a diminution equal to the increase of the Hippuric acid. As urea is one of the ultimate products of oxidation in the body, whilst Hippuric acid is very imperfectly oxidised, it would seem that during violent exertion the due oxidation of the secondary nitrogenous compounds produced by the disintegration of the tissues is interfered with, perhaps by the diversion of the oxygen to form carbonic acid, the quantity of which has been shown by Dr. Ed. Smith to be so notably increased by all kinds of muscular exertion; or we may, with more probability, suppose that the lungs are unable to eliminate the whole of the carbon of the disintegrated tissues in the form of CO_2, and that a part of the carbon is consequently discharged by the kidneys in the form of the richly-carbonized compounds, Hippuric or Benzoic acids. The quantity of Hippuric acid eliminated can be greatly increased by the administration of benzoic, succinic, cinnamic, or kinic acids, or of oil of bitter almonds.† The transformation of benzoic into Hippuric acid appears to take place at the liver, as it does not occur in jaundiced patients, or in dogs in whom the ductus communis choledochus has been tied, the Benzoic acid then passing off unchanged. The process is exceedingly simple. Benzoic acid ($C_7H_6O_2$) + Glycin (C_2H_5NO) or Glycocol ($C_2H_5NO_2$) producing Hippuric acid ($C_9H_9NO_3$) + $2H_2O$. Kühne and Hallwachs, however, maintain that the conversion occurs in the blood, and Meissner and Sheppard at the kidney.—*Kreatin* ($C_4H_9N_3O_2 + H_2O$) and *Kreatinin* ($C_4H_7N_3O$) may be obtained by the action of Chloride of Zinc on concentrated urine; but the researches of Heintz‡ have shown that no Kreatin is present in fresh urine, that which was formerly obtained being in fact produced by the decomposition of the Chloride of Zinc compound, the Kreatinin of which takes up water and is converted into Kreatin.§ The quantity of Kreatinin daily eliminated by a healthy man, living on a good mixed diet, was found by Neubauer to vary from 9 to 20 grains. The maximum quantity is excreted on a flesh, the minimum on a farinaceous diet (Meissner, Voit). In dogs, exertion causes no increase. Kreatinin is the most powerful organic base in the body. Kreatin which is chiefly derived from the nervous system can be converted by boiling with Baryta water into Sarcosin and urea.‖—When ingested with the food it is either eliminated unchanged, or it is partially converted into Kreatinin.¶ The colouring matters of the urine appear to be derivatives of the biliary acids, and not of the biliary colouring matters, since Bogomoloff** and Heynsius and Campbell†† found that injection of the biliary acids into the blood increased the quantity of urinary colouring matter, whilst injection of biliary pigments was without effect. Masius, and Vanlair‡‡ thought they proceeded from the colouring matter of the bile which underwent conversion in the intestines into stercobilin, and was partially excreted in the fæces and

partially eliminated by the kidneys. Jaffe* considered stercobilin to be identical with urobilin, since the absorption striæ of its solutions is the same, and it gives the same beautiful green fluorescence with chloride of zinc. Maly† obtained from the intestines a substance to which he has applied the term Hydrobilirubin, which he considers to be a derivative of cholepyrrhin, and to undergo partial absorption.‡ They may all be regarded as modifications of one substance, *urobilin*, which gives a yellow or rose colour dichroising into pink with mineral acids, and presents an absorption stria between *b* and F.§ These bodies, as was also noticed by Carter,‖ present close analogies to the series of compounds of which indican forms the first member, and a blue colouring matter is sometimes generated in disease. The researches of Schunck and Carter long ago showed that indican was a constituent of healthy urine, and Prof. Senator (1877) found that it is contained in remarkable quantity in the urine of those who take little food and who vomit, or fail to digest what they consume. The greater the degree of anæmia, the more pronounced is the excretion of Indican. It is particularly abundant in those suffering from carcinoma of the stomach.¶ The extractives of the urine contain considerable proportions of carbon, whilst they are poor in nitrogen; so that their increase will be favoured by an excess of carbonaceous food, an imperfect action of the liver, and a low degree of respiration; whilst, on the other hand, a highly-azotized diet, especially if combined with active exercise, will tend to their reduction.—The odour of the urine appears to be due to the presence of minute quantities of the volatile acids, termed by Städeler, Phenylic (or Carbolic, C_6H_5OOH), Taurylic ($C_{14}H_8O_2$), Damaluric ($C_{14}H_{11}O_3H_2O$, and Damolic, the composition of which last is unknown. Béchamp has described a ferment under the name of "Nephrozymose" which can be obtained from urine by precipitating it with three times its volume of alcohol of 90 per cent. It is an albuminous body, and is capable of converting starch into sugar at a temp. of 60°–70° C.

369. The determination of the mode and place of origin of the urinary constituents, and especially of the urea and uric acid, are points of considerable interest. The solution of this question, however, demands great skill in chemical analysis, and the evidence is at present in an extremely unsatisfactory state. As regards the *mode* of origin of urea, its composition shows clearly that it proceeds from the disintegration of the albuminous or nitrogenous constituents of the tissues and blood. It was at one time considered that it was generated entirely at the expense of the muscular tissue; but as no one has yet succeeded in extracting urea from muscle, and as muscular exertion, even when violent and protracted, causes little or no increase in the amount eliminated, and as the substances that we know result from the disintegration of muscular tissue, as kreatin and kreatinin, and either not at all, or not easily, converted into urea, and even when ingested are eliminated, unchanged, without causing any augmentation in the amount of urea, whilst a large increase quickly follows the ingestion of nitrogenous food when the body is at rest, there seem to be good grounds for admitting that only a portion of the urea discharged can proceed from that disintegration to which the muscles, in common with

¶ "Medical Examiner," August 7, 1877.

all other animal structures of high organization, are liable, and that another, and much larger portion is derived from the decomposition and disintegration of the albuminous compounds that are constantly being consumed in maintaining the activity of the great glandular and cellular organs of the body,* the ultimate results of the oxidation—urea, carbonic acid, and water—being the same. Numerous experimenters† have recently endeavoured to solve the question by examination of the urine in reference to the amount of urea eliminated after the administration of acids; of alkalies, especially of salts of ammonia, and of substances standing in more or less intimate chemical relationship with urea, such as the amido-acids and asparagin; and the most important outcome of these experiments seems to be that the production of urea and uric acid are not altogether the result of analytical processes, but that they proceed in part from synthetical processes. Hellerworden, for example, concluded from his experiments that the formation of ammonia precedes that of urea, and that a part of the ammonia is applied to the neutralisation of acids, whilst the excess is converted into urea. Schmiedeberg fed dogs with ethylamin carbonate, and obtained crystals of ethyl-urea; and he has hence been led to maintain that all compounds which contain the group NH_2—CH_2—are decomposed in the body with separation of ammonia, which then passes into the condition of carbonate, and finally by synthesis into urea.

The question of the *place* of origin of the urea is still more difficult to answer. Up to a very recent period it was universally held that the kidneys constituted a kind of filter by which certain products of the disintegration of the tissues were separated from the blood and discharged from the body. M. Picard's experiments, which showed that urea is uniformly present in the blood (2-4 parts in 10,000), and in larger proportion in the renal arterial than in venous blood, and those of Gréhant,‡ showing that after ligature of the ureters the amount of urea in renal venous blood becomes exactly equal to that in renal arterial blood, have been commonly referred to in support of this view, the small quantity present being attributed to the care with which the system was freed from this excretory product. Lately, however, an attempt has been made to prove that urea is formed from the secondary products of the disintegration of the tissues, such as kreatin, kreatinin, uric acid, hypoxanthin, and taurin, in and by the kidney itself, upon the following grounds.§—First, that extirpation of the kidneys is followed by only a trifling increase in the proportion of urea present in the blood, though the proportion of kreatin and other lower stages of the oxidation of nitrogenous compounds is augmented both in the blood and muscles; secondly, that after ligature of the ureters, the renal

* On this view the "luxus consumption" of Voit and others, which was considered to consist in the oxidation of the nitrogenous constituents of the food in the blood previous to their conversion into tissue, has no existence.

§ See Munk, "Deutsche Klinik," 1862, p. 299; Oppler, Virchow's "Archiv," 1861, Band xxi. p. 260; Subotin, Henle and Meissner's "Zeitschrift," Band xxviii. 1866, p. 114; and Zalesky, "Untersuchungen über den Uræmischen Process." Schultzen and Nencki ("Zeits. f. Biologie," 1872, Band vii. p. 124) believe that some of the intermediate stages between Albumin and Urea are represented by Glycol, Leucin, and Tyrosin. But Küssner has clearly shown that Tyrosin cannot be regarded as an antecedent of Urea ("Centralblatt," 1875, p. 216).

organs remaining intact, there is considerable increase in the amount of urea contained in the blood; thirdly, that the ingestion of kreatin with the food produces an increase of the excretion of kreatinin and urea; fourthly, that on rubbing down kreatin with the substance of the kidney, it is rapidly converted into urea; and lastly, that there is reason for believing that the cells covering the glomeruli, exercise a secreting function, and are not merely adapted for the elimination of water, since these glomeruli are abundantly distributed through the kidneys of birds, the urine of which animals is semi-solid, whilst it is impossible to obtain a trace of uric acid from their blood. Now, in opposition to some of these statements are the observations of G. Meissner,* who, by analysing large quantities of blood, obtained unmistakable evidence of the presence of uric acid in that of the bird (goose), and shows by calculation that it is possible for all the uric acid excreted by the animal to have been separated from the blood passing through the kidney in a given time. In the course of his experiments, Meissner found so much uric acid in the liver, and so little in other organs, that he came to the conclusion that the liver was the seat of its formation in birds.† On extending his researches to mammals, he found that here also the liver presented on chemical analysis a larger proportion of the essential urinary constituent urea than any other organ. Hence he concludes that it proceeds from the disintegration of the hæmoglobin of effete blood-corpuscles into urea, glycogen, and biliary colouring matter; and adduces pathological evidence, derived from the observations of Frerichs, Städeler, and Harley, to the effect that in acute and chronic atrophy of the liver it is either greatly diminished or wholly absent. Heynsius further adduced in support of this view the fact that more urea can be obtained from a liver which has been removed from the body for some hours and kept at a temperature of 104° F. than from a fresh one, and Cyon‡ maintained that the blood which was passed through the liver of a living animal is richer in urea after its passage than before. These statements have, however, been again called in question by Gscheidlen in an elaborate essay§ upon the subject, and his experiments have led him to the conclusion that no single organ can be fixed upon as exclusively producing urea, but that it is formed in the system generally. It is remarkable that though it can be detected in the blood, liver, spleen, kidneys, brain, and eye, it does not appear to be present in the muscles. Gréhant‖ finds that after extirpation of the kidneys, the amount of urea in the blood undergoes progressive increase, proportionate in fact to the quantity that would have been excreted had the kidneys been in action; he finds also that after ligature of both ureters the same accumulation of urea takes place, and that the renal venous blood, contrary to Picard's statement, contains less urea than renal arterial blood, whilst after ligature of both ureters the proportion of urea in the arterial and renal venous blood is equal. There seems therefore to be good reason for believing that urea is simply excreted by, and not formed in, the kidneys.¶ In reference to the origin of urea from kreatin, Meissner states, in opposition to Munk,** that he has found no increase in the

* "Centralblatt," 1868, pp. 226 and 275.

† Pawlinoff ("Centralblatt," 1873, p. 241) has satisfied himself that uric acid is not formed in, but only excreted by, the kidneys.

amount of urea when kreatin or kreatinin were given with the food, or otherwise introduced into the blood. In all instances these substances were discharged either unaltered, or merely with conversion of some of the kreatin into kreatinin. Voit* also declares himself opposed to the view that the formation of urea occurs at the kidneys, except in so far as that it may take place to some slight extent from a conversion of kreatin; though when this was given with food it was eliminated partly unchanged and partly converted into kreatinin. He found an increase in the quantity of urea in the blood, and also discovered it in the muscles, both after extirpation of the kidneys and after ligature of the ureters: the amount being larger in proportion to the lateness of the period at which death occurred, and on that account it was smaller in amount after ablation of the kidneys. In one instance, after extirpation had been performed, he collected the whole of the retained urea, and obtained 5·3 grammes, whilst, if the animal had been allowed to live, he would have eliminated 5·8 grammes in the same space of time. No increase of kreatin occurred either after extirpation or ligature. Respiration of oxygen diminishes the quantity of urea in the urine,† though it augments the activity of the combustive processes, and might therefore be expected to increase it. An explanation of this may be that it leads to the combustion of the urea itself and its conversion into carbonic acid, ammonia, and water, The non-increase of urea in the urine when violent exertion is made is, perhaps, explicable on the same view. On the whole, the results of recent researches seem to show that urea is formed in the tissues generally, including the renal, and with the exception perhaps of the muscular, and that thus entering the blood from many quarters, it is filtered off by the kidneys, the secreting cells of which have a special affinity for it.

370. Besides its organic materials, the urine contains a considerable amount of *Saline* matter; the excretion of which, in a state of solution, appears to be one of the principal offices of the kidney. The total quantity of fixed salts eliminated per diem by men on mixed diet varies from 140 grains to 378 grains, and by women from 158 to 303 grains. Various saline compounds are being continually introduced with the food; and others are formed within the system, by the oxidation of the sulphur and phosphorus of the tissues or of the food, and by the combination of the sulphuric and phosphoric acids thus formed, with alkaline and earthy bases which the food may contain, usually in a state of combination with weaker acids which are otherwise disposed-of. Thus the saline compounds found in the urine are to be regarded as partly proceeding from the retrograde metamorphosis of the materials of the tissues after these have served their purpose in the economy, and partly from that of such components of the food as, being superfluous, do not undergo organization. But the kidney also serves as the channel for the elimination of saline compounds introduced into the system *per se;* these being sometimes normally present in the body, but ingested in too large an amount, as is often the case with common salt; whilst, on the other hand, they may be altogether foreign to the composition alike of its solids and its fluids.—The *Alkaline Sulphates* usually constitute, as we have seen (§ 366), at least 10 per cent. of the whole solid matter of the urine. Being always in solution, however, they never make their presence known by the formation of sediments, and are only to be detected by chemical tests. The causes which influence their amount have been carefully studied by Dr. Bence Jones, who has shown that they vary (like urea) with the amount of food ingested, and with the degree of nervo-muscular activity put-forth; as might be anticipated from the fact, that, under

* "Centralblatt," 1868, p. 468. † Ritter, "Revue Scientif.," 1872, p. 91.

ordinary circumstances, the sulphuric acid is entirely formed within the system, by the oxidation of the sulphur of the protein-compounds, the bases being furnished by the alkaline carbonates or phosphates of the blood. A portion of the sulphur is, however, eliminated by the bowels in the form of taurin. In Mr. Weston's case the average excretion of sulphuric acid for five days before his long walk of 317½ miles in five days was 38·37 grains, for the five days of the walk 53.50 grains, and for the five days after the walk 49·02 grains. In regard to the effects of exercise on the excretion of acids by the urine, Klüpfel* found that it was augmented to the extent of 44·8 per cent. by exercise, whilst Sawicki† obtained only variable and chiefly negative results. When sulphuric acid or soluble sulphates are taken into the system *per se*, they partly find their way out of it by the kidneys; the proportion of sulphuric acid in the urine being for a time augmented, although the increase is not considerable until some hours have elapsed after the introduction of these substances into the stomach.‡ They are not increased on a non-nitrogenous diet by exercise (Parkes). The absolute amount of sulphuric acid varies from 35 to 50 grains per diem. Normal human urine contains more *phosphoric acid* than is required for the salination of the lime and magnesia bases in the urine. The normal amount eliminated per diem is from 30 to 40 grains. It is more abundant after animal than after vegetable food. The acid is ordinarily generated within the system, by the oxidation of the phosphorus originally introduced in the protein-compounds; and thus, as in the case of the sulphates, the quantity of its salts which is excreted by the urine bears a certain relation to the amount of these compounds ingested as food, and also to the amount of muscular tissue which has undergone disintegration by exercise. But it further appears that there is a special relation between the quantity of the alkaline phosphates in the urine, and the amount of disintegration of the *nervous* tissue; as might have been suspected from the fact, that this tissue is distinguished by the very large proportion of phosphorus, united with fatty acids, which it contains. And a marked increase of these salts is observed in those inflammatory diseases of the brain, in which there is reason to believe that an unusually-rapid disintegration of its texture is taking place.§—The *Earthy Phosphates* usually bear but a small proportion to the alkaline; but their presence in the urine comes to be of great importance with reference to the precipitates which they form in particular conditions of that secretion. From the researches of Dr. Bence Jones (loc. cit.) it appears, that the quantity of these phosphates in the urine chiefly varies with the amount of them contained in the food, into many articles of which they enter largely,‖ but he has also ascertained that their formation within the system is determined by the presence of their bases; for if any earthy salt, a little chloride of calcium or sulphate of magnesia, for

* Hoppe-Seyler's "Chem. Unters.," 1868, Heft 3. † Pflüger's "Archiv," Band v. p. 285.
‡ Dr. Bence Jones in "Philosophical Transactions," 1849.

§ See Dr. Bence Jones' valuable series of Papers in the "Philosophical Transactions" for 1845, 1847, and 1850, and in the "Medico-Chirurgical Transactions" for 1847 and 1850: also Byasson, Op. cit., p. 612. It is curious to observe, that whilst the increase in the alkaline phosphates in Inflammatory affections of the nervous centres is very marked, there appears to be a positive diminution of them in Delirium Tremens. A certain allowance must be made, however, for the abstinence from food, which will of itself occasion a reduction in the quantity excreted.

‖ The experiments of Neubauer ("Journal f. pract. Chem.," 1866, p. 96), Riesel (Hoppe-Seyler, "Med. Chem. Untersuch.," Heft 3, 1869), and Soborow ("Centralblatt, f. d. Med. Wiss.," 1872, p. 609) all show that when taken in excess the salts of lime are very rapidly and completely eliminated by the urine, the whole being discharged in the course of a few hours.

instance, be taken into the system, the quantity of earthy phosphates in the urine undergoes an increase. The small quantity of carbonate of lime taken into the system with the food, or set-free by the slow disintegration of the osseous tissue, is probably excreted in Man almost entirely in the form of phosphate; although of the much larger amount ingested by herbivorous animals, a considerable proportion is excreted in the urine in its original state. The Earthy Phosphates, although insoluble in water, are soluble in all acid liquids; and they are held in solution in Urine, like the urates, by the acid phosphate of soda. Their precipitation in an alkaline state of the urine is owing to the want of this solvent, not to an excess in their production; for as Dr Bence Jones has pointed out, that excess of alkaline and earthy phosphates in the urine which constitutes the true 'phosphatic diathesis,' is generally coincident with a highly-acid state of the urine. In Mr. Weston's case before alluded to the average secretion of the phosphoric acid was 50·14 grains per diem for the five days before the walk, for the five days of the walk 76·63 grains, and for the five days after the walk, 56·89 grains. The excretion of phosphoric acid is not increased by exercise on a non-nitrogenous diet (Parkes). The absolute amount excreted per diem on a mixed diet varies from 54 to 78 grains (Genth).—The only other inorganic saline constituent of the Urine, whose quantity gives it importance, is *Chloride of Sodium*. By far the larger proportion of this is doubtless derived directly from the food; but little being furnished by the disintegration of muscle, which will set free potash rather than soda. The amount eliminated by the urine is consequently subject to great variation, the function of the Kidneys being to remove whatever is superfluous, and thus to prevent the blood being overcharged with this substance. The average quantity is 250 grains, but in Ranke's experiments on his own person, the quantity discharged varied from 75 to 523 grains daily. Of the chloride of sodium introduced as food, a part appears to undergo decomposition in the system, whereby hydrochloric acid is furnished to the gastric fluid, and soda to the bile; much of this acid, however, must reunite with its base in the alimentary canal, so that the chloride of sodium thus regenerated will be absorbed with the products of the digestive operation. Its quantity is increased by muscular exertion (Byasson). Dr. Flint found the average amount daily excreted during five days in the person of Mr. Weston to be 159·45 grains for 5 days previous to a walk of 317½ miles. During the walk the average was 65·08 grains, and during the five days after the walk 312·40 grains per diem. The quantity is decreased on a non-nitrogenous diet (Parkes.) It is much diminished after profuse sweating (Ranke), and in many diseases, especially in inflammation of the lungs. In febrile affections the potassium salts are eliminated in larger proportion than those of sodium. In convalescence the opposite prevails.* The amount of *Ammonia* excreted by the urine varies from 0·83 to 0·61 grammes (12·8—9·4 grains) per diem.† The administration of the mineral acids augments the quantity considerably,‡ the increased production of ammonia having the advantage of preventing the acids introduced into the system from combining with and carrying off the fixed alkalies, the presence of which is so indispensable for life,§ and lending some support to the view of Schmiedeberg,‖ that in the decomposition of the tissues ammonia is first formed and then urea.—

‖ "Archiv f. Exper. Pathol. und Pharmacol.," Band viii. 1878, p. 9.

Although *Nitric Acid* can scarcely be regarded as a normal constituent of the Urine, yet the investigations of Dr. Bence Jones* appear to show that it is formed by a combustive process within the body, whenever ammoniacal salts are introduced into the system; its amount, however, being very small. He has also found that it is generated after the ingestion of small quantities of urea; a fact which affords some confirmation to the doctrine of Frerichs, that urea may undergo decomposition into carbonate of ammonia, whilst still circulating in the current of blood.—The presence of *Oxalic Acid* in the urine (in combination with Lime) has been usually regarded as a pathological phenomenon, consequent upon an irregular performance of the retrograde metamorphosis of the tissues; but there can be no doubt that it may also result from the presence of soluble salts of oxalic acid in certain articles of vegetable food.†—The Gases found in the urine have been examined by Planer‡ and Bernard.§ Planer found in one instance 7, and in another 16 per cent. of gas. The following Table gives the percentage composition of the gases obtained:—

In 100 parts of Urine at 32° F. and 30 in. Bar.		Percentage Composition of the Gases amongst themselves.		
		Planer.		Bernard.
Nitrogen	0·820	15·2	7·2	18·64
Oxygen	0·043	0·5	0.5	2·55
Carbonic Acid free	4·729	84·3	92·3	78·81
„ „ combined	3·066			
		100	100	100

About one-third of the carbonic acid was combined, the remaining two-thirds were free.

371. The ordinary *acid* reaction of the Urine appears to be due, not to the presence of any free acid, but to the conversion of the *basic* phosphate of soda into the *acid* phosphate by the subtraction of a part of the base, which occurs when uric, hippuric, lactic, or other free acids come into contact with the former substance. There is no adequate reason to believe, that, in the healthy state, there is ever any other cause than this; although in morbid urine free organic acids are almost certainly present.‖ The urine becomes more acid after elimination, the reason of which is not known. It has been shown¶ that the acid reaction is far from being constant in degree, even when an ordinary mixed diet is steadily employed; for that it varies at different periods of the day, increasing and decreasing *inversely with the acidity of the stomach.* Thus the acidity of the Urine decreases soon after taking food, whilst that of the Stomach is increasing, and attains its lowest limit about three to five hours after a meal, when, therefore, absorption is being most actively performed. An alkaline reaction is often observed in the

* "Philosophical Transactions," 1851.—It is right to state, however, that this doctrine has been called in question by some eminent authorities, who deny the validity of the test for nitric acid employed by Dr. Bence Jones.

urine at this period, which, according to Dr. Roberts, is due to the presence of fixed alkali; this occasions a precipitation of earthy phosphates, rendering the urine turbid, though the quantity of uric acid at this period is always large. The acidity then gradually increases, whilst that of the stomach is decreasing; and attains its highest limit after a fast of some hours, when the stomach is quite empty, and its secretion neutral. If no food be taken, the acidity does not decrease, but remains at nearly the same point for ten or twelve hours. When *animal* food was alone employed, the diminution of the acidity after a meal was more marked and continued longer than when a mixed diet was eaten (apparently on account of the greater demand for acid in the stomach); and the acidity did not rise quite so high after fasting as with a mixed diet. On the other hand, when the diet was purely *vegetable*, the diminution of the acidity of the urine was never such as to render it absolutely alkaline, although its acidity was reduced to the point of neutrality; and the increase of its acidity after fasting was sometimes very considerable, though by no means so marked as the decrease of alkalescence.—These diurnal variations in the acidity of the urine make it highly probable that corresponding variations occur in the alkalescence of the blood; such diurnal variations being produced by the quantity of acid separated from it, and poured into the stomach for the purpose of dissolving the food. The introduction of dilute sulphuric acid into the stomach, even in large doses, was not found to produce any decided change in the acidity of the urine; the only perceptible effect being a slight diminution of the decrease which takes place after taking food, and a slight augmentation of the increase after fasting. On the other hand, the use of liquor potassæ in large doses lessens the acidity of the urine, preventing it from rising after fasting to the height it would otherwise attain, and increasing its alkalescence after a meal; but it does not render the urine by any means constantly alkaline, nor does it hinder the variations produced by the state of the stomach from being very evident. Tartaric acid in large doses temporarily increases the acidity of the urine, causing it to rise considerably higher than usual after a fast, but not preventing that which is passsed a few hours after food from becoming alkaline. Tartrate of potash in large doses, on the other hand, has a marked effect in rendering the urine alkalescent; still it does not prevent the usual recurrence of the acidity some hours after a meal.—The Urine of Herbivorous animals, except during inanition,* is *alkaline;* partly because their food contains a large quantity of alkaline and earthy bases, in combination with citric, tartaric, oxalic, and other acids, which are decomposed within the system; and partly because the amount of sulphuric and phosphoric acids, generated as products of the oxidation of the elements of the tissues or of the surplus-food, is not sufficient to neutralize them. Such is the condition which occasions the alkalinity of Human Urine, when a portion of the acid which would otherwise show a predominance is directed into another channel; and it is exaggerated in those states, in which, either from the irritating nature of the food, or from the irritable condition of the stomach, an undue quantity of acid is poured out into that viscus; so that, its reaction being habitually acid, that of the urine becomes habitually alkaline. Such a state of the urine must be carefully distinguished, as Dr. Bence Jones has pointed out,† from that in which the alkalescence is due to the presence of *volatile*, and not to that of *fixed* alkali; the difference being easily recognizable by the influence of the liquid upon reddened litmus-paper, for the restoration of

* The hippuric acid naturally present is then replaced by uric acid.

† "Medical Times," Dec. 13, 1851.

its blue colour is permanent in the latter case, but only transitory in the former. The alkalescence due to the presence of volatile alkali is due to the decomposition of urea, whilst the urine is yet within the bladder, through the agency of morbid secretions of that viscus; and it disappears when this organ returns to its healthy state. On the other hand, the alkalescence from fixed alkali proceeds from disordered action of the stomach, which is usually connected with disorder of the general system; and it persists until this can be remedied. In both forms of alkalescence there is a precipitation of earthy phosphates; but in the alkalescence from fixed alkali the precipitate usually consists almost entirely of phosphate of lime: whilst in that from volatile alkali, the amorphous sediment of phosphate of lime is mingled with prismatic crystals of the phosphate of ammonia and magnesia. These precipitates may be obtained from healthy urine, by adding to it a solution of potash or of ammonia; and the decomposition of such urine, which begins to take place very soon after it leaves the body, gives rise to the same precipitation, by the production of carbonate of ammonia, at the expense of its urea.

372. Thus, then, we have seen that the Kidneys serve as the special instruments for depurating the Blood of those *highly-azotized* compounds, which are formed in the system by the decomposition of the materials of the albuminous and gelatinous tissues, and also by that of the non-assimilated components of the food. We have seen, also, that they serve for the removal of certain excrementitious compounds, of which *carbon* is a principal ingredient; and these, although normally present in but small amount, may undergo a marked increase in disease, especially when the liver is insufficiently performing its functions, or the respiratory process is obstructed. Further, we have been led to regard the Kidneys as the emunctory, not only for the superfluous water of the blood, but also for those saline compounds, which, having been introduced into the system or generated within it, in larger amount than is compatible with the normal constitution of the blood, or than is required for the reparation of the solids of the body, or for the production of its fluid secretions, are only fitted for elimination. On this point a very elaborate series of researches was made by Wöhler,* who showed that of the soluble salts taken into the circulation, those are most readily excreted which produce a determination of blood towards the kidneys, whereby an increased quantity of liquid is filtered-off through the outlet which they afford. This statement is to be extended from saline compounds, to such other soluble matters as are not eliminated by preference through other channels, or are present in too large an amount to find their way out thence with sufficient rapidity, as Sugar and Lactic acid. In like manner, too, the system makes an effort to free itself (so to speak) from various substances altogether foreign to it, which have been introduced into the circulating current by absorption, and which would be injurious if retained; the rate at which it does so being in a great degree dependent upon the functional activity of the Kidneys.

373. It is a most important fact, in a Dietetic and Therapeutic point of view, that the metamorphic process, of which the greater part of the constituents of the urine are the products, should be capable of retardation or of acceleration by the presence of other substances in the blood. The former appears to be the operation of *thein*, which is the active principle of Tea and Coffee. From various experiments,† it appears that the use of these substances, by retarding the "waste" of the system, diminishes the demand for

* Müller's "Elements of Physiology," translated by Baly, p. 589.

† Böcker, "Archiv des Vereins für gem. Arbeit. zur Förd. der Wiss. Heilk.," 1854; and Julius Lehmann, "Annal. der Chem. und Pharm.," Band lxxxviii.

food, and makes a limited amount of it go further;* and this conclusion seems fully borne out by experience.†—The like results happen, according to Dr. Böcker, under the use of small quantities of Alcohol frequently repeated; as much as 13⅓ grammes less urea being excreted daily, when a teaspoonful of proof spirit was taken seven or eight times a day, than when water alone was drunk. It does not hence follow, however, that Alcohol can be used as advantageously for this purpose as Tea or Coffee; in fact, it may be doubted whether it is so much by diminishing the "waste" of matter, as by interfering with the due elimination of its products, that Alcohol occasions a diminution in the weight of the urinary solids. For, although it does not appear to effect any marked diminution, but rather an increase in the elimination of certain forms of excrementitious matter which have been received back into the blood, and especially of the hydrocarbonaceous products (§ 287, vi.), yet very cogent evidence is supplied by the experience of Zymotic diseases, that the very same cause produces an accumulation of fermentible azotized substances in the blood.—It seems not unlikely that the almost instinctive craving for Tobacco among a large proportion of mankind arises out of its possession of a power of retarding the metamorphosis of the tissues; since we find that men, when supplied with this article, can far better sustain being put upon a short allowance of food than when destitute of it.

374. Of the substances that accelerate the metamorphosis of the tissues, and thus augment the solids of the urine, the Alkalies and their carbonates and Chloride of Sodium are those whose action is best known; these (with such of their salts as are formed by acids which are decomposed in the blood into the carbonic, such as the acetates, tartrates, and citrates) have a solvent action on the albuminous compounds generally, and tend to break-up these compounds into simpler forms of combination. Hence it seems likely that their presence in the Blood in increased amount will tend to hasten the retrograde metamorphosis of the tissues; their chemical force being exerted, not merely upon those which are already in a state of disintegration, but also upon those which, being disposed to degenerate, cannot exercise that resisting power which they possess when in a state of complete vital activity.‡ The operation of Liquor Potassæ in health, in acute rheumatism, and in chronic diseases, has been carefully studied by Dr. Parkes,§ and he has given satisfactory evidence that it causes an increase in the solids of the urine generally, but especially in the urea and in the amount of the sulphuric and phosphoric acids; thus clearly showing that it hastens the metamorphosis of some of the albuminous structures of the body. Similar results were obtained by Dr. Golding Bird,‖ from the employment of acetate of potash.—It does not appear, however, that the excretion of the urinary solids is augmented by those "diuretic" medicines which cause a large amount of liquid to be passed-off through the Kidneys, merely by determining an increased flow of blood to them. On the contrary, it would seem as if, by producing congestion and irritation, they sometimes interfere with the normal process of secretion;

* Dr. Ed. Smith ("Proceed. of Roy. Soc.," 1861) found the decrease in the elimination of urea after the use of tea (which had the greatest effect) and coffee to be but slightly marked after the first day or two.

† Voit, from experiments with coffee on a *dog*, was led to a different result; and considers that this substance possesses but little influence on the excretion of urea. See Henle and Meissner, "Bericht," 1860, p. 397.

‡ See Voit, "On the Action of Common Salt," &c., Munich, 1860.

so that the quantity of solid constituents is actually decreased, notwithstanding the large augmentation in the watery part of the urine.* This very important fact has been demonstrated by Prof. Krahmer,† who gives the following as the result of his observations upon the amounts excreted in 24 hours, after the administration of diuretics to persons in health :—

Medicine given.	*Total Solids in Urine.*	*Organic Compounds.*	*Inorganic Compounds.*
None	2·40 oz.	1·28 oz.	1·13 oz.

It seems highly probable that the 'critical evacuations' of urine, as of sweat or fæcal matter, on which the older physicians were accustomed to lay great stress, are really charged with noxious substances, of which the blood is thus depurated; and that great benefit would frequently arise in practice from the use of the 'alterative diuretics,' as suggested by Dr. G. Bird, where (as in chronic rheumatism, gout, &c.) there is reason to believe that a quantity of mal-assimilated matter exists in the system, of which it is important to get rid. In many such cases, indeed, clinical observation had already established the benefit derivable from such medicines, without affording the rationale of it.

375. The urine as it is secreted trickles drop by drop into the bladder, a musculo-membranous receptacle capable of holding from one to three pints, from which it is discharged at stated periods. The bladder is composed of two muscles opposed in action, the detrusor urinæ, which forms the greater part of the membranous bag, and the sphincter vesicæ, which forms its neck. Both are chiefly composed of unstriated muscular tissue, though some fasciculi of striated muscle are found in the sphincter, and both are under the governance of nervous centres situated in the lumbar portion of the spinal cord, though they may also be influenced by the emotions and the will. Under ordinary circumstances the escape of the urine is prevented by the moderate contraction or tone of the sphincter vesicæ, to overcome which in the rabbit the pressure of a column of water of from 16-20 inches in height,‡ and in the dog of about 30 inches is required. On section of the lower part of the spinal cord, or of the vesical nerves, the pressure of a column of water of only five or six inches in height is sufficient to force a passage for the fluid through the sphincter. The concordant observations of Masius§ and Budge‖ show that the motor centre of the bladder is situated at or about the level of the 4th lumbar Vertebra in animals. In connection with the motor centre there appears to be a second or inhibitory centre also situated in the lumbar region, for Goltz has shown¶ and observations on man furnish corroborative evidence that neither incontinence nor retention of urine need necessarily follow division of the spinal cord; but that in some instances the subjects of this injury can hold their water for several hours, and discharge it at regular intervals—that is to say, that whilst the bladder is filling, some influence restraining the action of the detrusor is exerted, which

* In the case of Digitalis Dr. Brunton found there was a considerable absolute, though not relative, increase in the amount of urea eliminated. See Brunton on "Digitalis," p. 42, 1868.

† Heller's "Archiv," Dec. 1847. ‡ Kupressow, Pflüger's "Archiv," 1872, Band v. p. 291.

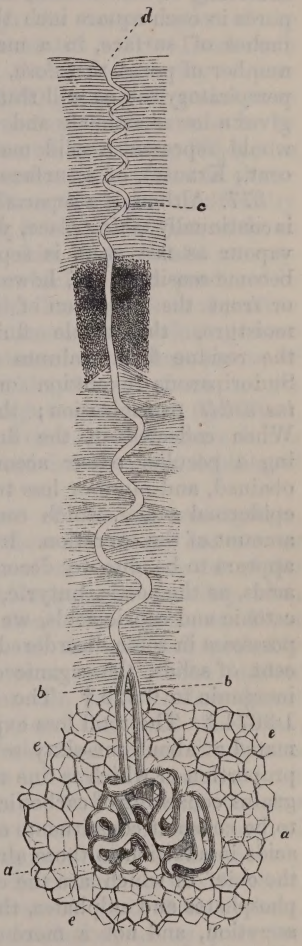
from analogy there is reason to believe proceeds from an inhibitory centre, till the excitation of the accumulated urine becomes so strong as to stimulate the motor centre and overpower the inhibitory centre. Goltz observed, and the experiment might be useful in cases of lesion of the spinal cord in man, that the application of a cold wet sponge to the anus caused immediate expulsion of the urine, either by stimulating the motor centre and inducing contraction of the detrusor, or by paralysing the inhibitory centre, and thus effecting the relaxation of the sphincter, and removing any obstacle to the respondence of the detrusor to the stimulus of the moderate accumulation of urine in the bladder. Daily experience teaches us that the will can exert an influence both on the motor and inhibitory centres situated in the lumbar region of the cord.

4. *Of the Skin;—Cutaneous Transpiration.*

376. The Skin is the seat of various secretions, as the Sebaceous, Ceruminous, and Odoriferous,—for each of which it is provided with special organs; but these have reference chiefly to its own protection, or to some other *local* purpose; and the only one which can be regarded as truly *excrementitious*, is the Transpiration of aqueous fluid holding certain matters in solution. The elimination of this fluid from the blood is effected by the *Sudoriparous* glandulæ (Fig. 180), which essentially consist of long convoluted tubes (*a*, *a*), rarely single, but usually multiplied by repeated dichotomous subdivision (*b*), sometimes also giving off short cæcal processes before their termination. These are seated beneath the Corium and in the midst of the subcutaneous adipose tissue rather than in the substance of the skin itself, and the glomerulus is always invested by a sheath of smooth muscular tissue (Krause).* The tubuli of each gland are lined with one or more layers of polyhedric epithelial cells, and unite so as to form but one duct; and this passes upwards through the Cutis and Cuticle, in a somewhat cork-screw like manner (*c*), to open upon the surface of the latter (*d*), which it usually reaches obliquely, so that the outer layer of the Epidermis forms a sort of little valve, which is lifted by the secreted fluid as it issues forth. These glandulæ are diffused in varying proportions over the entire surface of the body. According to Mr. Erasmus Wilson,† as many as 3528 of them exist in a square inch of surface on the palm of the hand; and since every tube,

Fig. 180.



Sudoriparous Gland from the palm of the hand, magnified 40 diam.:—*a*, *a*, contorted tubes, composing the gland, and uniting in two excretory ducts, *b*, *b*, which unite into one spiral canal that perforates the epidermis at *c*, and opens on its surface at *d*; the gland is imbedded in fat-vesicles, which are seen at *e*, *e*.

* Krause, "Centralblatt f. d. Med. Wiss.," 1873, p. 817.

† "On the Management of the Skin," 3rd edit., p. 37.

when straightened-out, is about a quarter of an inch in length, it follows that, in a square inch of skin from the palm of the hand, there exists a length of tube equal to 882 inches, or 73½ feet. The number of glandulæ in other parts of the Skin is sometimes greater, but is generally less than this; and, according to Mr. Wilson, about 2800 may be taken as the average number of pores in each square inch throughout the body. Now the number of square inches of surface, in a man of ordinary stature, is about 2500; the total number of pores, therefore, may be about *seven millions*; and the length of the perspiratory tubing will thus be 1,570,000 inches, or nearly 28 miles. Landois gives a lower estimate and estimates the number at about 2½ millions, which would represent a solid mass about equal to one-third of a kidney (77 cub. cent., Krause), or a surface of about 40 square inches.

377. Although a separation of fluid by this extensive glandular apparatus is continually taking place, yet this fluid, being usually carried off in the form of vapour as fast as it is separated, does not ordinarily accumulate so as to become sensible. If, however, from the increased amount of the secretion, or from the condition of the surrounding air as regards temperature and moisture, the whole fluid thus poured out should not evaporate, the residue forms minute drops upon the surface of the skin. Thus the Sudoriparous excretion may take the form either of *sensible* or of *insensible* transpiration; the latter being constant, the former occasional. When collected in the fluid state, sweat is a colourless liquid, possessing a peculiar odour according to the part of the skin from which it is obained, and more or less turbid from the presence of sebaceous matter and epidermal scales, which constitute from 0·2 to 0·3 per cent. of the whole amount of the excretion. Its reaction is alkaline.* The acidity often observed appears to be due to decomposition, and to the presence of certain volatile acids, as the acetic, butyric, and formic; to which, and possibly to the metacetonic and capric acids, we are probably to attribute the sour smell which it possesses in some disordered states of the system. It contains about 1·29 per cent. of solids, the organic constituents amounting to 0·962 per cent. and the inorganic to 0·329.† The index of refraction of sweat from the axilla is 1·3674.‡ The total loss experienced by an adult through the skin is estimated at about one-sixty-seventh of the weight of the body, by far the larger proportion of which is due to the elimination of water, only from 50 to 150 grains consisting of carbonic acid gas. The substances which have been found to be constant constituents of the sweat are, water, fat, various volatile fatty acids in addition to those already mentioned, urea and inorganic salts, amongst the chief of which are the chlorides of sodium and potassium, the alkaline phosphates and sulphates, the earthy phosphates, and iron. That it is a true secretion, and not a mere transudate, is shown by the entire absence of albumin, except under very unusual conditions, and then only occasionally.§ Other constituents of the sweat, whose presence is not constant, or the nature of which has not been satisfactorily determined, are the salts of ammonia, of lactic acid, and of the hydrotic acid of Favre, and certain pigmentary sub-

* Gillibert d'Hércourt, "Gaz. Méd. de Lyon," 1853, Trümpy, Pflüger's "Archiv," xviii. p. 494.

† The proportion of solid matter contained in different specimens differs very greatly; thus, according to Anselmino, it varies between 0·5 and 1·25 parts in 100; the observations of Favre ("Archives Génér. de Méd.," 1853, 5me Sér., tom. ii. pp. 1–12) give ·443 parts per 100 as the proportion contained in nearly nine gallons which he had collected; whilst those of Schottin ("Archiv für Physiol. Heilkunde," Band ii. pp. 73–104) raise it as high as 2·24 parts per 100, of which, however, 1·2 parts consisted of epithelium and insoluble matters.

§ See Leube, Virchow's "Archiv," Band xlviii. pp. 181, 301; and "Archiv f. Klin. Med.," Band vii. p. 1.

stances of various shades. In disease, uric acid, grape-sugar, albumin, and biliary colouring matters have been found; and when taken with the food, benzoic acid (partly converted into hippuric), succinic, cinnamic, and tartaric acids, arsenious and arsenic acids, with iodine and iodide of potassium, have been recovered in the sweat. Funke calculates that about 11 grains of nitrogen are daily eliminated by the skin through the desquamation of the epithelial scales. He also found urea (as was first stated by Dr. Landerer*) to be a constant constituent. In one experiment, the entire quantity of perspiration for the whole body, for 1 hour, being 3320 grains, $6\frac{1}{2}$ grains were found to be present. If the secretion had continued at the same rate for 24 hours, $157\frac{1}{2}$ grains of urea would have been eliminated, containing $73\frac{1}{2}$ grains of nitrogen. Under ordinary circumstances, however, it is probable that a very much smaller quantity is thus eliminated. From the general uniformity in the proportion of solids in the fluid eliminated, it is obvious that, with an increase in the quantity of fluid excreted by the skin, there is also an augmented excretion of solids; and to the deficiency which is thus produced in the salts of the blood may be partly assigned the debilitating effects of profuse perspirations. Other causes, however, probably concur in producing those effects. Thus the great fatigue which is experienced as a consequence of muscular exertion in a heated atmosphere may fairly be set down to the diminished activity of the respiratory process at high temperatures (§ 287, 1), and the colliquative sweating of hectic fever is obviously not a cause but a consequence of, though it may also react upon and increase the debilitated state of the general system.

The secretion of sweat is under the influence of the nervous system, and the researches of Luchsinger† and others show that there are one or more sweat centres situated in the anterior horns of the grey matter of the spinal cord, and extending into the medulla oblongata, or possibly even lying in the cerebral convolutions. From these centres nerve fibres arise, which, in the case of the *posterior limbs* of the cat, and probably in other animals and man, emerge with the anterior roots of the lumbar nerves, especially with the second and third, but also with the last dorsal roots, and enter the cord of the great sympathetic, and then join the sciatic nerve, being ultimately distributed to the skin of the foot. Some fibres also emerge from the last lumbar and the sacral nerves and join the sciatic without first passing into the sympathetic system (Vulpian). The fibres for the *fore limbs* chiefly emerge with the anterior roots of third, fourth, and fifth cervical nerves, and join the first thoracic ganglion of the sympathetic, or pass directly into the branches of the brachial plexus to be distributed to the forefoot. The sweat centres may be excited by mental influences, as by fear, by heat, by venous blood, as in Asphyxia, by reflex stimulation, as by irritation applied to the leg of the opposite side or to other sensory nerves, and by various toxic agencies, as by Jaborandi or its active principle Pilocarpin, by Eserin, Picrotoxin, Nicotin, and Ammonium, Acetum, and by Muscarin. They are inhibited by cold and by Atropin. Stimulation of the centres or of the nerves causes a great and sudden increase in the amount of secretion produced, but no such effects are observed if the nerves be divided below the

point stimulated. On the other hand, on stimulation of the distal cut extremity the secretion immediately recommences, even when the temperature is low, and without any increase in the capillary circulation, showing that the secretion is not the result of simple transudation consequent on congestion of the vessels, but to the action of special gland cells. So entirely independent is it of the vascular system that it can be induced by appropriate stimulation even in a limb that has been severed from the body. If the abdominal sympathetic cord be cut in an animal on one side, and the creature be exposed to heat, no sweating occurs, but if the distal surface of the divided trunk be stimulated, sweat is exuded on the foot of the same side; but, if now the sciatic be divided, stimulation of the sympathetic fails to produce any further secretion. In man the secretion is always bilateral and symmetrical.

378. The entire loss by the Skin in 24 hours is 1-67th of the total weight. The amount of fluid which is "insensibly" lost from the Cutaneous and Pulmonary surfaces was estimated by Seguin at 18 grains per minute; of which 11 grains pass off by the skin, and 7 by the lungs. Funke,* with two students, made numerous experiments upon the amount and characters of the Sweats excreted from the hand and forearm under different circumstances. In these experiments the arm was enclosed in a caoutchouc bag, and each experiment lasted for one or two hours. It was found that the largest quantity of sweat obtained from the forearm and hand under favourable circumstances, in 1 hour, was 740 grains, which would, in 24 hours, supposing the secretion to continue at the same rate, amount to about $2\frac{1}{2}$ lbs. But, from accurate measurements, Funke ascertained that the ratio of the superficies of the forearm and hand to that of the body generally was 1 : 17; so that if the perspiration took place continuously and at the same rate from the whole surface of the body, upwards of 42 lbs. might be discharged in 24 hours. On the other hand, the minimum quantity excreted by the hand and forearm was 48 grains per hour, which would amount to 1152 grains in 24 hours, and this, multiplied by 17, would give $2\frac{3}{4}$ lbs. for the amount eliminated from the whole body in 24 hours. It was found, however, that different regions of the body gave off, in proportion to their surface, very different quantities of fluid: thus, in no instance was the amount discharged by the leg equal to that given off by the arm. Moreover, the three experimenters furnished very different proportions of sweat under the same circumstances: thus, with active exercise in the sun, the proportion between them was as 1 : 2·3 : 4·4, and in another experiment as 1 : 1·7 : 2·06. Funke draws the conclusion from his experiments, that the entire amount of perspiration from the whole body may fluctuate from about 2 ounces (819 grains) to about 29 ounces (12,588 grains) per hour, the quantity of solid residue varying from 14·25 to 107·57 grains per hour. Favre, by taking large quantities of warm drinks, and exposing the body to a high temperature, collected no less than 2560 grammes, or about $5\frac{1}{2}$ lbs. of water in $1\frac{1}{2}$ hours. It is difficult to give an average for the 24 hours when the variations are so great; but it may, perhaps, be estimated at about 2 lbs., the exhalation of aqueous vapour by the lungs being rather less than 1 lb. (§ 294). An interesting series of observations has been published by Dr. Victor Weyrich† upon the relative amounts of insensible perspiration under different conditions. The

† "Die unmerkliche Wasserverdünstung der Menschlichen Haut," Leipzig, 1862. See abstract in "Med.-Chir. Rev.," 1863, vol. ii. p. 359. See also Röhrig, "Die Physiologie der Hautathmung," "Deutsch Klinik," 1872, No. 23; and Erismann, 'Zur Physiologie der Wasserverdünstung von der Haut,' in "Zeitschrift f. Biologie," Band xi. pp. 1–78, 1875.

instrument he employed was a modification of Daniell's hygrometer; and his experiments extended over more than a year. He found that variations of temperature between 55° and 70° F., when the body was clothed, produced little effect; but every 1° C. (= $1\frac{4}{5}$° F.) above 70° F. occasioned an increase of 2 per cent. in the total amount of vapour exhaled, and for every 1° C. below 55° F. there was a diminution of from 1 to $1\frac{1}{2}$ per cent. He observed that the effects of the relative moisture of the air were in great measure concealed by variations in temperature, so that the highest averages of insensible perspiration occurred, not with the lowest, but with moderate amounts of moisture in the air. The minimum amount of perspiration always occurred on rising in the morning, being then 25 per cent. below the average. The maximum amount was eliminated at noon, when it rose to 52 per cent. above the minimum. Food invariably increased the cutaneous transpiration, coffee and tea having a particularly powerful influence. The increase occurred soonest after breakfast, but was greatest and most permanent after dinner. Moderate muscular or mental exertion slightly increased the amount of perspiration, but fatigue and exhaustion produced a considerable decrease. Violent muscular effort raised it to 77 per cent. above the mean; severe intellectual labour, 42 per cent. During sweating, the rise was equal to 116 per cent. over the mean, but after sweating it fell even to 26 per cent. below the mean. The amount of insensible perspiration varies greatly, with the conditions of the atmosphere, and of the body itself, in respect to exposure, food, exercise, and activity of other secretions; and these variations, as we shall hereafter see (§ 381), have a most important share in the regulation of the temperature of the body. According to Garrod* sweating begins when standing at rest at about 86° Fahr. Exact observations on this point, however, in which not merely the temperature, but the hygrometric state of the air should be precisely determined, are much wanting; the best hitherto recorded being those made by Dr. Southwood Smith† at the Phœnix Gas Works, in which the former element only was carefully noted. These observations were made upon eight of the workmen employed in 'drawing' and 'charging' the retorts and in making up the fires, during which they are exposed to intense heat; the men were accurately weighed in their clothes, immediately before they began, and after they had finished their work; and in the interval between the first and second weighings, they were not allowed to partake of any solid or liquid *ingesta*, nor to part with urine or fæces.

Experiment I. Nov. 18, 1836. Day bright and clear. Temperature of the air in which the men worked, 60° Fahr. Barometer 29·25 in. to 29·4 in. Duration of labour, 45 minutes.—Average loss of weight, 3 lbs. 6 oz.; maximum, 4 lbs. 3 oz.; minimum, 2 lbs. 8 oz.

Experiment II. Nov. 25, 1836. Day foggy, with scarcely any wind. Temperature of the air 39° Fahr. Barometer 29·8. Duration of labour, 75 minutes. Average loss of weight, 2 lbs. 2 oz.; maximum, 2 lbs. 15 oz.; minimum, 14 oz.

Experiment III. June 3, 1837. Day exceedingly bright and clear, with little wind. Temperature of the air, 60°. Duration of labour, 60 minutes.—Average loss of weight, 2 lbs. 8 oz.; maximum, 3 lbs.; minimum, 2 lbs.

Experiment IV. On the same day two other men worked in an unusually hot place for 70 minutes; the loss of weight of one of these was 4 lbs. 14 oz.; and of the other 5 lbs. 2 oz.

* "Journ. of Anat. and Phys.," vol. vi. 1872, p. 130.

† "Philosophy of Health," vol. ii. pp. 391–396.

Although the individuals subjected to those experiments were not in all instances the same, yet there was enough of identity among them to admit of the certain inference, that the amount of fluid lost must be influenced by the state of the individual system, as well as by that of the surrounding medium. Thus, in the second experiment, Michael Griffiths lost 2 lbs. 6 oz., and Charles Cahell 2 lbs. 15 oz.; whilst in the third, Michael Griffiths lost 3 lbs., and Charles Cahell only 2 lbs. It is probable that the amount of liquid ingested not long previously might have a considerable influence on the quantity lost by transpiration under such circumstances. The most recent investigator into the conditions affecting the evaporation of fluid from the body is Erismann,* who examined them both in the dead and in the living body. In the *dead body* he found that the amount of fluid evaporating from a given area of the skin was the same whether the under surface was in contact with serum or with water, and whether the vessels were fully injected with water or not. The amount increased rapidly with temperature and with the dryness of the air, but it made little difference whether 1000 or 6000 litres of air passed over the surface in a given time. Evaporation took place most actively from those parts which contain the sweat-glands; the skin of the sole of the foot, for example, which contains, according to Krause, 2685 sweat-glands in the square inch, yielding nearly double the amount of insensible perspiration as compared with the skin of the belly, which has only 1136 in that area, notwithstanding the much greater thickness of the epithelium in the former situation. A dead body (the size of which is not given) of a woman lost 617·6 grains in 24 hours, the temperature being 63° F., and the amount of aqueous vapour in the air 64 per cent. (as compared with saturation). Experiments made upon the *living body* showed that the most important external factor in determining the amount of evaporation was the relative dryness or moisture of the air. Next came the temperature, and then the ventilation or amount of air blowing over the surface. The imbibition of a large quantity of hot fluid, by filling the vessels and increasing the pressure, augmented the evaporation. It was also increased by work, even though sweating did not occur. Considerable difference of opinion exists as to whether the insensible perspiration is discharged by the surface of the skin generally (Krause, Donders), or whether this is not the exclusive province of the sweat-glands. Erismann adduces many reasons in favour of the latter view, and it may at least be admitted that the greater part of the 'insensible' and all the 'sensible' perspiration is eliminated by these glands.

379. That the Cutaneous excretion is to a certain extent vicarious with the Urinary in regard to the amount of fluid eliminated, has been generally admitted, and is probably true; but the observations of Weyrich have shown that under similar conditions, avoiding extremes, both excretions rise and fall together, and that, consequently, no deductions can be drawn as to the amount of perspiration given-off from any estimates of the volume of urine discharged. We must not disregard the circumstance, however, that these two excretions are to a certain extent vicarious, in regard to the elimination of the products of the 'waste' of the system. Leube† has in particular shown that in certain affections of the kidneys the skin exudes urea, phosphoric acid, and chlorine in excess, whilst the quantity of these compounds appearing in the urine is correspondingly diminished. The share which the Skin has in this office has probably been generally underrated. As we have seen (§ 377), there is reason

* Erismann, 'Zur Physiologie der Wasserverdünstung von der Haut,' in the "Zeitschrift f. Biologie," Band xi. 1875, pp. 1–78.

† "Deutsche Archiv f. Klin. Med.," Band vii. p. 1.

to believe that a certain amount of azotized matter is excreted from it daily; and any cause which checks this excretion must throw additional labour on the kidneys, and will be likely to produce disorder of their function.—From the experiments of Aubert, it would appear that the proportion of Carbonic acid eliminated by the Skin is to that discharged by the Lungs as 1 : 200, whilst the amount of oxygen absorbed is as 1 : 180. Reinhard* estimates the daily amount of Carbonic Acid eliminated by the whole skin of an adult, by calculation from experiments made on one of his arms, at from 33 to 36 grains, and Röhrig found that the Skin of one arm yielded half a grain of Carbonic Acid gas per hour. The secreting action of the Skin is influenced by general conditions of the vascular and nervous systems, which are as yet ill understood. It is quite certain, however, that through the influence of the latter the secretion may be excited or suspended; this is seen on the one hand in the state of syncope, and in the effects of depressing emotions, especially fear, and its more aggravated condition, terror; and on the other, in the dry condition of the skin during states of high nervous excitement. It is possible that, in forms of fever, the suppression of the perspiration is a cause, as well as an effect, of disordered vascular action; for there are several morbid conditions of large parts of the surface, in which the suppression of the transpiration appears to be one of the chief sources of danger, having a tendency to produce congestion and inflammation of the internal organs. The operation of some poisons, like tobacco and jaborandi, induces copious sweating. From the experiments of Dr. Fourcault,† which have been confirmed by Valentin,‡ it appears that complete suppression of the perspiration in animals, by means of a varnish applied over the skin, gives rise to a state termed by him 'cutaneous asphyxia;' which is marked by imperfect arterialization of the blood, and considerable fall of temperature; which is probably the cause of death in the lower animals§. A partial suppression by the same means gives rise to febrile symptoms, and to albuminuria. Other symptoms that have been observed are tremors, hyperæsthesia, and subsequently anæsthesia of the skin, increased reflex excitability, tetanic cramps, movements of rotation of the whole body, paralysis of the bladder (Feinberg), ulcers in the stomach in consequence of extensive extravasations and diffuse parenchymatous inflammation of the kidneys (Socoloff).‖ In Valentin's experiments it was found that removal to a room of high temperature (71° to 140° Fahr.) was followed by remarkable temporary improvement in the condition of the animals, sensibility and voluntary motor power being reacquired, and in some instances food being taken. Death, however, always ultimately occurred. Laschkewitsch¶ regards the effects produced as analogous to those seen in paralysis of the vaso-motor nerves, where a hyperæmic condition of the vessels is present, and the animal loses heat rapidly, and more in proportion to the smallness of its size. He denies that the cause of death is asphyxia, but attributes it to cold, and refers in support of his view to the fact that death may be deferred or prevented by wrapping the animal in cotton wool. Lang** has pointed out that crystals of the triple phosphates which he attributes to the decomposition of urea may be found in all parts of the body after death

** "Archiv d. Heilkunde," 1872, Band xiii. p. 277.

by suppression of the perspiration. He considers the animals die from uræmic poisoning. Feinberg,* on the other hand, refers the symptoms to the irritation of the cutaneous nerves caused by the stiffening of the varnish, which leads to vascular disturbances and paralysis, and secondarily to an affection of the spinal cord. The poisonous nature of the cutaneous secretion is well shown in an experiment made by Rohrig,† who found that the injection at noon of $3\frac{1}{2}$ ccm. of fresh filtered human sweat into the external jugular vein of a rabbit caused the temperature to rise from 99·2° F. to 104·3° during the evening, whilst the pulse rose from 192 per minute to 326, and the respiration from 82 to 105. On the following morning, the temperature remaining the same, the cardiac beats were 315, and the respirations 215 in the minute; after that it gradually returned to the normal in the course of the day. During the febrile state the urine contained albumin. There can be no doubt whatever, that imperfect action of the Cutaneous glandulæ, consequent upon inactive habits of life and want of ablution, is a very frequent source of disorder of the general system; occasioning the accumulation of that decomposing organic matter in the blood, which it is the special office of these glandulæ to eliminate. Hence the due maintenance of health requires that this excretion should be promoted by the use of the natural and appropriate means just referred-to; and this is the more necessary, when from any cause the function of the kidneys is imperfectly performed. There are many diseased states, moreover, in which there appears to be a special determination of the *materies morbi* to the Skin; and in which, therefore, the use of means that promote the cutaneous excretion constitutes the most efficient method of eliminating it from the blood.‡

CHAPTER XII.

EVOLUTION OF HEAT, LIGHT, AND ELECTRICITY.

1. *General Considerations.*

380. The series of Nutritive operations which has now been passed in review has been shown to consist in the continual appropriation, by the Animal organism, of certain 'organic compounds' or 'alimentary materials,' which have been generated for its use by Plants; and in the constant restoration of their elements to the Inorganic world, either in the very same forms of combination in which they originally existed there, or as products of incipient decay, by whose further decomposition those simple binary compounds will be reproduced. And thus, so far as the material components of the Organic Creation are concerned, the agency of of vegetable life is employed in withdrawing them from the Mineral world, and that of Animal life in returning them to it, after they have served their purpose in the living structure. But if we examine into the source of those active powers or 'forces,' on whose

* "Centralblatt f. d. Med. Wiss.," 1873, p. 545.

† 'Beiträge zur Physiologie der Haut,' "Jahrb. f. Balneologie," 1873, Band i. p. 1.

‡ The practical value of active diaphoresis in many febrile diseases, is well understood by the native practitioners among the Negroes of the Guinea Coast; who, according to Dr. Daniell ("Medical Topography and Native Diseases of the Gulf of Guinea," pp. 119–20), make use of it most successfully in the treatment of adynamic remittent fevers. Dr. Daniell states that having himself had abundant experience of its efficacy, he has no doubt of its superiority in these cases to the ordinary practice of venesection, saline purgatives, large doses of calomel, &c. And he has repeatedly stated that one great secret of preserving health in tropical climates, lies in due attention to the cutaneous functions.

operation every change, no less in the organized body, than in what is commonly designated as 'inert' matter, is dependent, we shall find that they are all traceable to the solar radiations. It is by the action of the Light and Heat of the Sun upon the Vegetable germ, that it is enabled to exercise its wonderful transforming capacity, whereby it extracts carbon, hydrogen, nitrogen, and oxygen, from the carbonic acid, water, and ammonia furnished by the atmosphere or the soil; and that it converts these into the albuminous, saccharine, and oleaginous compounds, which are the destined food of Animals.* And it is under the influence of Heat chiefly derived from the same source, that the greater number of tribes of Animals are enabled to apply these compounds to the purposes of organization; and that, through the peculiar instruments thus constructed, those various kinds of *Vital Force* are evolved, whose operations are so different from any which we witness in the Inorganic world. Accordingly we observe that the 'rate of life' in this larger proportion of the Animal Kingdom, is regulated, as in Plants, by the amount of Heat supplied to the organism from external sources; and that, when the external temperature is reduced below a certain point, there is an entire cessation of all vital activity. But there are certain tribes, especially Birds and Mammals, which possess the power of generating *Heat* within themselves, to such a degree as to render the rate of their vital processes almost entirely independent of external influences; and there is probably no one species that can exercise this power more effectually, and through a greater range of external conditions, than Man is able to do. Of this we shall presently have evidence.—The evolution of *Light*, again, is by no means an unusual phenomenon among the lower tribes of Animals; but where it does occur, it usually appears to have some special purpose, as is obvious enough in the case of the glow-worm and other luminous Insects. But the luminosity which is occasionally exhibited in Man must be regarded as an altogether abnormal phenomenon, whose physiological interest arises out of the peculiarity of the circumstances under which it presents itself.—Of the degree in which *Electricity* is generated in the living body, we know comparatively little. There can be no doubt that a disturbance of Electric polarity takes place in every action of Organic as well as of Inorganic Chemistry: and that every molecular change in the Animal as well as in the Vegetable organism must involve an alteration in its electric condition. But it would seem that in the Animal body generally, these alterations are made to balance each other so exactly, that no considerable disturbance of the electric equilibrium ordinarily takes place in the organism as a whole; and it is only in certain peculiar cases (as in the Electric Fishes) that a provision exists for the generation of Electricity in considerable amount and intensity, with a view to some special purpose. In the Human subject, however, an extraordinary production of free electricity, as of Light, occasionally presents itself; and this, taken in connection with other evidence, would seem rather to indicate a departure from the *balance* usually maintained between the opposite electrical changes continually taking place, than to be due to the introduction of any extraordinary sources of electric disturbance.

2. *Evolution of Heat.*

381. All the vital actions of the body of Man, as of that of 'warm-blooded' animals generally, require an elevated temperature as a condition of their performance; and the high degree of constancy and regularity which is observable in these actions, appears to depend in great degree upon the provision which the organism contains within itself, for the maintenance of that tempera-

* See Engelmann, Pflüger's "Archiv," Band xix. 1879, p. 1.

ture at a fixed standard. This constancy and regularity are most remarkably exhibited in the various *periodical* changes to which the body is subject both in health and in disease; the uniformity of whose recurrence is due to a corresponding uniformity in the rate of vital action taking place in the interval. Thus, as will be shown hereafter, the period of parturition is in great degree determined by the maturation of the fœtal structures; and the uniformity of the time which this requires (like the corresponding uniformity in the period of development in the embryo-bird) may be fairly attributed to the regularity of the supply of Heat, which is the power that especially determines the formative operations. For the periods of all similar phenomena in 'cold-blooded' animals, which have comparatively but feeble power of maintaining an independent temperature, exhibit no such uniformity; yet even in the lowest Vertebrata, according to Mr. Gulliver,* the temperature of the body is from 2° to 5° warmer than that of the medium in which they live. Heat, which is a mode of motion, is generated whenever stronger chemical affinities than those which were previously in action are satisfied; hence the temperature rises in muscles that are made to contract, and in glands when they are in the active performance of their function. The liver, spleen, kidneys, and glands of the intestinal tube,† with the brain,‡ the muscles during exercise, and the blood§ itself are the chief generators of heat in the body, because in all these parts active processes of oxidation are taking place by which the constituents of these organs and tissues are reduced to lower and more stable planes of composition leading to a certain amount of force being set free in the form of heat. We shall now inquire, in the first place, into the amount of heat thus generated by Man; and then into the sources of its production.

382. Our present knowledge of the ordinary Temperature of the Human Body, under different circumstances, is due to the investigations of a multitude of observers, references to many of which will be found in Wunderlich's exhaustive treatise.‖ A series of observations made by Dr. J. Davy¶ included 114 individuals of both sexes, of different ages, and among various races and different latitudes, and under various temperatures; the external temperature, however, was in no instance very low, and the variations were by no means extreme. The mean of the ages of all the individuals was 27 years. The following is a general statement of the results, the temperature of the body having been ascertained by a thermometer placed under the tongue:—

Temperature of the air	60°	Average temperature of the body	98·28°
,, ,,	69°	,, ,, ,,	98·15°
,, ,,	78°	,, ,, ,,	98·85°
,, ,,	79·5°	,, ,, ,,	99·21°
,, ,,	80°	,, ,, ,,	99·67°
,, ,,	82°	,, ,, ,,	99·9°
Mean of all the experiments . .	74°	Mean of all the experiments . .	100°
Highest temperature of air . . .	82°	Highest temperature of body .	102°
Lowest temperature of air . . .	60°	Lowest temperature of body . .	96·5°

‖ Wunderlich's treatise has been translated by Dr. Woodman for the New Syd. Society. See also Brown-Séquard ("Journal de la Physiologie," 1859, p. 549), whose experiments essentially corroborate those of Dr. Davy, as well as the older ones of MM. Eydoux and Souleyet ("Comptes Rendus," 1838, p. 457), except that he found a greater difference in the temperature of the men he examined, though the variation of the atmospheric temperature was much less. E. Oertmann (Pflüger's "Archiv," Band xvi. 1878, p. 101) has lately suggested the introduction of the thermometer into the stream of urine escaping from the urethra during micturition, as a rapid means of ascertaining the temperature of the interior of the body with accuracy.

¶ See "Anatomical and Physiological Researches."

From this we see that the variations noted by Dr. Davy, which were evidently in part the consequence of variations in external temperature, but which were also partly attributable to individual peculiarities, amounted to $5\frac{1}{2}$ degrees; the lower extreme might be found to undergo still further depression, if the inquiries were carried on in very cold climates. Wunderlich* gives as the result of the numerous observations made by himself and others of late years, a lower mean temperature than Dr. Davy, and states that the range of normal temperature in the axilla is from 97·25° Fahr. to 99·5° F., and that the *mean normal temperature* is 98·6° F. Climate appears to have very little influence on the temperature of the healthy adult white man. Hence a much larger absolute amount of heat must be generated in the body in cold climates and with low external temperatures.† The temperature of the natives of India is said to be a little higher than the mean.‡ It is also higher in Icelanders,§ whilst it is as much as 2·5° F. lower in Africans.‖ It is slightly higher in women. A slight increase occurs during the last two months of pregnancy,¶ and an augmentation of 0·3° F. has been observed *during* labour pains. Amongst the most important of these variations that occur in the temperature of the body are those dependent upon Age, Period of the Day, Exercise or Repose, Ingestion of Food or Drink, and External Temperature.

1. The temperature of *Infants* just born, according to the observations of Andral, Dr. Davy, M. Roger,** and Dr. G. C. Holland,†† is somewhat higher than that of adults,‡‡ provided that they are placed in conditions favourable to its sustenance; but, as will be shown hereafter, infants and young children are very inferior to adults in their power of resisting the depressing influence of external cold. Their temperature before birth is a trifle higher than that of the mother's uterus or vagina.§§ When examined immediately after birth by a thermometer in the axilla, it is nearly 100°; but it quickly (2 hours‖‖) falls to about 95·5°, and gradually rises in the course of the next twenty-four hours to about 97·7° in weakly subjects, and to 99·5° in strong infants. Between four months and six years of age. M. Roger found the average temperature to be 98·9°; and, between six and fourteen years of age, 99·16°. Dr. Finlayson¶¶ states that from 300 observations made on children he satisfied himself that in them there was a minimum from about 10 P.M. to 3 A.M., a gradual rise during the early morning hours, a maximum during the day, and a tolerably rapid fall during the early part of the evening. The average range of temperature amounted to more than 3° Fahr., and this variation he believes cannot be explained by reference to the diurnal range in the temperature of the air, to the influence of daylight, of muscular exertion, of food,

‡‡ Dr. W. F. Edwards ("On the Influence of Physical Agents on Life," p. 115) gives as the result of his observations, which were only ten in number, that the temperature of infants is lower than that stated above; but it is obvious that these observations were made during the period of depression which occurs in the first few days, whilst the respiratory function is becoming established.

‖‖ Dr. J. Maclagan, "Transact. Roy. Soc. of Edinb.," 1870; abstract in "Lancet," Aug. 13th, 1870, p. 243. ¶¶ In a paper read before the Phil. Soc. of Glasgow, Dec. 3rd, 1873.

or of sleep, but is simply an expression of a law of daily periodicity affecting the body.*—The Temperature of *aged* persons, from the observations of Dr. J. Davy, does not seem to be below that of persons in the vigour of life, provided that there be no external depressing influences; but they seem, like infants and young children, to have less power of resisting external cold, the temperature of their bodies being more easily and considerably reduced by it than is that of adults; and hence probably it has happened that popular opinion assigns to them an habitually inferior temperature.

II. A slight *diurnal* variation in the temperature of the body appears usually to take place, quite irrespectively of external heat or cold; but this does not seem to be very constant either in its period or its degree, and is seldom very considerable. The concurrent observations of many observers show† that the body is warmer in the morning and colder at night. Dr. Ogle found that the temperature rose from morning till late in the afternoon, after which it fell till bedtime. The lowest temperature occurred about daybreak. The average diurnal variation was about 1·5° Fahr. The minimum temperature noticed was 97° at 5.30 A.M., in winter. The maximum was 100·6° whilst in a Turkish bath of 120°. The extreme oscillation of temperature, therefore, was not more than 3·5° F. in health. Dr. Jürgensen found the diurnal variation to amount to from 1·8° to 3·6° F.; the minimum occurred from 1.30 A.M. to 7.30. The temperature then, with some fluctuation, rose till 4 P.M., when it attained its maximum, which lasted till 9 P.M., and after this it again fell. Dr. Casey found his mean temperature during the day to be 98·07 F., the mean range of temperature 1·61° F. The maximum range 2·5°. The maximum temperature was at 7.30 P.M. Sidney Ringer and P. Stewart give the average maximum temperature for persons under twenty-five years of age at 99·1° F., of those over forty 98·8° F. They find the period of highest temperature extends from 9 A.M. till 6 P.M.; the lowest is about midnight. These observations correspond well with what has already been pointed out with regard to the relative activity of the respiration (§ 287, VIII. and IX.), and circulation at different periods of the twenty-four hours. As a rule the temperature of the two sides of the body is alike, but Blake‡ has observed that the right side is sometimes as much as 1° F. higher than the left during exertion, especially in the sun.

III. That an increase in the heat of the body is produced by *exercise*, and that repose tends to its reduction, is a matter of familiar experience; but the observations of Dr. Davy show that there is scarcely any perceptible difference in the heat of the deep-seated parts, the augmentation and depression being confined to the extremities. Thus, on one occasion recorded by him, the temperature of the air of the room before walking being 60°, that of the feet (shown by a thermometer placed between the toes) being only 66°, that of the thermometer under the tongue being 98°, and that of the urine being 100°, —the temperature after a walk in the open air at 40°, the exercise having diffused a feeling of gentle warmth through the body, was 96·5° in the

* Sitz ("Jahrb. f. Kind.-heilk.," Band iv. 1871, p. 414) is in accord with Finlayson.

† Davy, loc. cit., W. Ogle, "St. George's Hospital Reports," vol. i. p. 221. Dr. Ogle's experiments were made on two healthy adults; the temperature being taken by introducing a warmed self-registering thermometer three or four times a day under the tongue, and retaining it in that position for several minutes. They extended over a year. Jürgensen, "Deutsches Archiv f. Klin. Med.," Band iii. p. 166. Dr. Jürgensen's experiments extended over three days, and consisted in reading off at intervals of five minutes the indications of a thermometer permanently retained in the rectum at a depth of about two inches. Casey, "Lancet," vol. i. 1873, p. 200. See also Ringer, "Proceed. of the Roy. Soc.," vol. xvii. p. 287.

‡ E. Blake, "Med. Times and Gazette," Oct. 1871.

feet, 97° in the hands, 98° under the tongue, and 101° in the urine. So, on another occasion, the temperature having been 66° in the room, 75° in the feet, 81° in the hands, 98° under the tongue, and 100° in the urine,—after a walk in air at 50° the temperature was 99° in the feet, 98° in the hands, 98° under the tongue, and 101·5° in the urine. These effects are, therefore, in all probability, chiefly due to an increase in the energy and frequency of the heart's contractions, by which means the warm blood is driven with greater velocity through the extreme capillaries, imparting its heat to the surrounding parts. Marcet* found in the ascent of Mont Blanc that when at rest the temperature of the body did not vary very much at different heights. In the ascent, as Lortet† observed, the internal temperature of the body fell during exercise, especially when the stomach was empty and the skin was freely perspiring—to a degree, indeed, that was almost proportional to the height ascended. When the feeling of malaise, so often complained of by Alpine travellers, or *mal de montagne*, was most evident, the temperature was lowest, and the sensation was best removed and the temperature raised by frequent ingestion of food. The observations of Clifford Allbutt‡ do not support the statements of Lortet, for he found that, with one or two exceptions, the tendency of exercise in Alpine climbing was to elevate the temperature. The forenoon rise occurred earlier, and the evening fall had often reached the night-level at 9 P.M. The difference was probably owing to the different physique of the two observers. Passive movement (swinging or rocking for fifteen minutes) was found by Manassein§ to lower the temperature of rabbits about 1° Fahr., even when they were carefully protected from draught. The depression reached its maximum half an hour after the swinging had ceased, and lasted for two hours. The experiments of various observers, moreover, have shown that a certain amount of heat is developed during the active contraction of muscular tissue, the rise in temperature of a muscle like the Biceps, after a few powerful contractions, being as much as 1° Fahr.; and this increase in temperature may be regarded as due to the increased energy of the chemical changes, and in some measure also to the mechanical effects of friction, &c., taking place in the contracting muscle.‖ It is remarkable that voluntary increase of the frequency and extent of the respiratory movements for the space of ten minutes, or suspension of the respiration at the end of a full inspiration, alike produce a decline in the temperature of the blood, as shown by that of the skin over the radial artery; in the former case amounting, in M. Lombard's¶ experiments, to as much as 2° Fahr. Drs. Wilson Philip, Hastings, and C. J. B. Williams have pointed out that here, just as in the performance of artificial respiration, the cooling effect of the air introduced is greater than the warming effect of the respiratory processes to which it becomes subservient. Coincidentally with such increase of the respiratory movements, however, there is diminution of the force and tension of the pulse, as shown by the sphygmograph, which may to some extent explain the fall. It thus appears that the temperature of the body is not raised by exercise to the extent that might be expected, its increase beyond a certain point being provided for by more rapid breathing, the quicker circulation of the blood through the skin, and consequently quicker cooling by radiation, sweating, &c., so that, as Wunderlich observes, the opposing condi-

tions of the loss of force by mechanical work and by quicker cooling, and on the other hand the overplus through augmented chemical action, compensate each other in health, *and the final difference of temperature during rest and during labour* is extremely trifling.

IV. The influence of *ingestion of food* upon the temperature of the body was found, in Dr. Ogle's and in Dr. Jürgensen's experiments, to cause a slight elevation of the temperature both of the mouth and of the rectum, unless wine were consumed, when a decline occurred. Dr. Jürgensen observed no change beyond a slight depression of the mean diurnal temperature after fasting for 26 hours; but when the abstinence was prolonged to a period of 62 hours, the mean diurnal temperature rose, and the usual period of depression did not occur. Drs. Ringer and Rickards* have shown that, excepting in those who are much accustomed to its use, the ingestion of alcohol in considerable doses causes a remarkable diminution of temperature, amounting in some cases to about 3° F. In rabbits, the injection of alcohol into the rectum caused a depression of the animal heat amounting to 15°. They found that alcohol in various doses produces only slight and temporary depression of the temperature of febrile persons; and consequently, that although when indicated, it will act to some extent beneficially in virtue of its power to cause some diminution of the temperature, yet it cannot bring the temperature of febrile persons to that of health. The experiments of Dr. W. Ogle,† and of Tscheschichin,‡ are confirmatory of the preceding results. Dr. Ogle found that tea caused an elevation of temperature. Common experience leads to the conclusion that after a meal, as after exercise, there is greater warmth in the extremities; but Dr. Davy's observations show that, in his own person, whilst resident in England, there was usually an appreciable depression immediately after dinner, though in Barbadoes the effect of a moderate meal was to produce an elevation. In both cases, however, Dr. Davy observed that the ingestion of *wine* had a positively-depressing influence on the temperature of the body, which increased with the quantity taken; and it may have been the constant employment of wine with his dinner which was the real cause of the depression observed in England.

V. The influence of *external temperature* is sufficiently apparent in the observations already cited; for although external cold may act in a different degree on different individuals, according to their respective ages, powers of resistance, &c.; sometimes, when its action is brief, causing a slight increase of temperature; yet there is ample proof that on the whole a continued exposure to it reduces the temperature of the body somewhat below its ordinary standard, whilst continued exposure to heat occasions a slight elevation in the temperature of the body. The influence of cold is, of course, most powerfully exerted when the body is at rest; and under such circumstances Dr. Davy found the temperature of his own body to be reduced, on an average of four observations, to 96·7° F., the average temperature of the surrounding air having been 37° F. On comparing the bodily temperature of different individuals working in rooms of various temperatures in the same factory, Dr. Davy found the tongue-thermometer rise to 100° F. in one man, and to 100·5° in another who had been working for some hours in a room at 92°; whilst it was 99° in a young woman who worked in a room at 73°, and only 97·5° in another who worked in a temperature of 60°. Dr. Schuster§ found the effects of baths of different kinds, as hot water and douche baths, was to cause an elevation of temperature, and to increase the rapidity of the pulse. Horvath, in experiments on

* "Proceed. of the Roy. Med.-Chir. Soc.," vol. v. 1866, p. 209. † Op. cit., p. 238.
‡ Reichert's "Archiv," 1866, p. 151. § Virchow's "Archiv," Band xliii. p. 60, 1868.

rabbits, found that when they are cooled down by snow to 73° F. the heart beats rarely, excitation of the vagus is inoperative, the intestines are motionless and non-excitable, asphyxiation causes neither augmentation of the blood-pressure nor cramps, but all these phenomena are reversed when the temperature is raised to 100° F.* The lowest temperature to which Horvath† succeeded in cooling puppies with subsequent restoration was 40° F. as measured by a thermometer in the rectum. The effects of seasonal change are less marked in man than they are in the lower animals, which are more exposed to extremes of temperature; but it seems principally exerted in modifying the heat-producing power. For it has been shown by Dr. W. F. Edwards that warm-blooded animals are more speedily killed by extreme cold in summer than in winter; and it seems probable, therefore, that we are partly to attribute the peculiar chilling influence of a cold day in summer, and the oppressiveness of a warm day in winter, to the seasonal change in the body itself; although the effect is doubtless referable in part to the effect of contrast upon our own feelings.‡ Budge states that during the spring months the temperature of the body is a little higher than in winter.

383. The influence of the nervous system upon the temperature of the body presents some interesting features. Local variations of temperature are effected essentially through the vaso-motor nerves, which for the most part run in the sympathetic system. Speaking generally, it may be said that stimulation of the vaso-motor nerves of any part by contracting the capillaries and diminishing the supply of blood, occasions a reduction of temperature in it, whilst paralysis or division of the vaso-motor system, by causing dilatation of the capillaries, leads to a more rapid circulation and a higher temperature. In accordance with this the effects of section of the spinal cord are not constant, for such lesion is sometimes followed by an elevation, and sometimes by a decline in the temperature. Thus, a case is recorded by Sir B. Brodie§ in which the spinal cord having been so seriously injured in the lower part of the *cervical* region that the whole of the nerves passing off below were completely paralysed, the heat of the body, as shown by a thermometer placed in the groin, was not less than 111° F.; and this, notwithstanding that the respiratory function was very imperfectly performed, the number of respirations being considerably reduced, and the face livid. Similar cases have been recorded by other observers. On the other hand, when the spinal cord has been divided experimentally in animals, Sir B. Brodie‖ and others have shown that

* Horvath, "Wien. Akad.," 1870, No. 11. † "Centralblatt," 1871, p. 513.

‡ Many of the lower animals, as the Marmot and Dormouse, hybernate during the winter, and their state has been very carefully examined by Valentin and by Horvath ("Centralblatt," 1872, pp. 706, 721, and 737). Horvath's experiments were conducted on Marmots (Spermophilus citillus), which exist in large quantities in Russia. In captivity he finds that during the winter they sleep for about four days and then wake for four days. During the sleeping period they can be cooled down to such a degree that a thermometer introduced into the rectum to the depth of an inch and a half indicated only 3° F. above the freezing point. The temperature rose rapidly after the animal awoke, so that in the course of an hour it was 3° F. higher, at the close of the second hour 9° F. higher, and at the end of the next half hour about 27° F. The cause of this remarkable elevation of temperature is according to Horvath scarcely explicable on the ordinary chemical theory of calorification, since neither the respiration nor the muscular movements were correspondingly augmented.

the temperature of the body usually falls with rapidity, even when artificial respiration is steadily maintained. This difference, however, is probably due to the secondary conditions of the experiment, for it is to be particularly noted that section of the cervical region of the spinal cord, providing peripheral cooling be prevented by suitable means, is followed by a marked rise of temperature, whilst division of the dorsal region of the cord is followed by depression of temperature. No rise of temperature occurs in the former case if the anterior columns be spared. Hence Fischer contended that an inhibitory or regulating centre for heat exists in the anterior columns of the cervical portions of the cord, stimulation of which caused depression, and paralysis of which was followed by increase of the body temperature. Erb considers it most reasonable to assume that in these experimental lesions there is a paralysis of certain parts which serve to restrict the production of heat. At the same time, however, an extensive vascular paralysis takes place, whereby an increased amount of heat is given off, which more or less compensates for the increased production. According to the preponderance of one or the other factor, the rise of temperature will be more or less considerable, or may be absent or even be a minus quantity. In M. Tscheschichin's experiments, section of the pneumogastrics was not observed to produce any remarkable effect upon the development or distribution of the animal heat in rabbits—at least not until those pathological conditions which have been already described (§ 282), as resulting from their section, had become established. Various pathological phenomena indicate that the withdrawal of nervous influence from any part of the body usually tends to produce a depression of its temperature, and this especially in the extremities; thus Mr. H. Earle* found the temperature of paralysed limbs slightly lower than that of sound limbs; so Prof. Dunglison has noticed that in one case of hemiplegia of five months' standing, the temperature of the axilla was 96½° on the sound side, and 96° on the paralysed; whilst that of the hand was 87° on the sound side, and only 79½° on the paralysed; and in another case of only a fortnight's duration, the temperature of the axilla was 100° on the sound side, and only 98¼° on the paralysed, whilst that of the hand was 94° on the sound side, and 90° on the paralysed.† According to Folet,‡ the temperature of the paralysed side soon after an attack of hemiplegia is 1·8 Fahr. above that of the opposite side; but, when atrophy supervenes, the temperature falls again. The elevation is quite independent of the seat of the lesion of the nervous system.

384. The usual temperature of the body occasionally undergoes considerable alteration in *disease;* and this in the way either of increase or of diminution. Thus in maladies which involve an acceleration of pulse and a quickening of the respiration, the temperature is generally higher than usual, even though a large portion of the lung may be unfit for its function. This is often remarkably seen in the last stages of phthisis, when the inspirations are extremely rapid,

f. d. Med. Wiss.," 1869, p. 259. Brown-Séquard, "Revue Scientif.," 1871, p. 288. The remarkable case recorded by Hutchinson, "Lancet," 1875, vol. i. p. 713; and that by Dr. Teale, already referred to. Heidenhain in Pflüger's "Archiv," Band iii. p. 504; and Weir Mitchell, Brown-Séquard's "Archives of Scient. and Pract. Med.," 1873, No. 4. Schreiber, Pflüger's "Archiv," Band viii. 1874, p. 576. Erb, Ziemssen's "Cyclopæd. of Pract. Med.," Amer. edit., vol. xii. p. 128, 1878. C. V. Schroff ("Centralblatt für die Med. Wiss.," 1877, p. 38) found that on dividing the spinal cord of a dog at the level of the seventh cervical vertebra, and enveloping the animal in wool, there was a fall of temperature during the first hour, amounting to 0°·6 C. A rise of 2°·9 C. occurred in the course of the next five or six hours, which was followed by a gradual fall coinciding with great acceleration of the respirations.

and the pulse so quick as scarcely to admit of being counted; the skin, in such cases, often becomes almost painfully hot. On the other hand, in diseases of the contrary character, such as "morbus cœruleus," asthma, and cholera, the temperature of the body falls; a very considerable reduction of temperature having been noticed in both maladies. The range observed by M. Andral in diseases which less affected the calorifying function, was from 95° to 107·6°; and by M. Roger (loc. cit.), in diseases of children, from 74·3 to 108·5. Professor Dunglison* speaks of having seen the thermometer at 106° in scarlatina and typhus; and Dr. Francis Home† found it to stand at 104° in two individuals in the cold stage of an intermittent, whilst it afterwards fell to 101°, and subsequently to 99°, during the sweating stage. Dr. Edwards mentions a case of tetanus, in which the temperature of the body rose to 110¾°. The following observations have been made on this subject by M. Donné:‡ in a case of puerperal fever, the pulse being 168, and the respirations 48 per minute, the temperature was 104°; in a case of hypertrophy of the heart, the pulse being 150, and the respirations 34, the temperature was 103°; in a case of typhoid fever, the pulse being 136, and the respirations 50, the temperature was 104°; and in a case of phthisis, the pulse being 140, and the respirations 62, the temperature was 102; on the other hand, in a case of jaundice, in which the pulse was but 52, the temperature was only 96·4°; but the same temperature was observed in a case of diabetes, in which the pulse was 84. These limited observations, whilst they clearly indicate that a *general* relation exists between the temperature of the body and the rapidity of the pulse, also show that this relation is by no means invariable, but that it is liable to be affected by several causes, of which our knowledge is as yet very slight. Persistent high temperature of the body (105°–110°) in febrile affections usually indicates a fatal issue. The highest temperature yet observed has been reported by Dr. J. Teale, of Scarborough, who in a case of injury to the spine from a fall registered the remarkable temperature of 122° Fahr., the pulse being 120.§ In this instance the patient recovered.‖ Jacobson,¶ from experiments made with thermo-electric instruments, has satisfied himself that the temperature of intensely inflamed skin and muscles never rises so high as the temperature of the inner parts of the body, which is quite in accordance with the dictum of John Hunter, that local inflammation cannot raise the temperature higher than the degree of warmth found at the centre of the circulation. It is still doubtful whether the augmented temperature observed in febrile diseases is due to diminished elimination or to increased production of heat, but considering the large excess of heat that is developed during the crisis of fevers there seems to be reason for believing that Leyden's view in favour of excessive production of heat is correct.** It is not a little remarkable that the temperature of the body should frequently *rise* considerably *after death;* and this not merely in such cases as Cholera, in which it has undergone an extreme depression during the latter part of life; but even in the case of febrile disorders, in which the temperature during life has been above the usual standard. This has been ascertained

by Dr. Bennet Dowler,* of New Orleans, on the bodies of those yellow-fever subjects which may be especially referred to as exhibiting a remarkable degree of *molecular* life after *somatic* death. In one case, for example, the highest temperature during life was in the axilla, 104°; ten minutes after death, it had risen to 109° in the axilla; fifteen minutes afterwards, it was 113° in an incision in the thigh; in twenty minutes, the liver gave 112°; in one hour and forty minutes, the heart gave 109°, and the thigh in the former incision 109°; and in three hours after the removal of all the viscera, a new incision in the thigh gave 110°. It is curious that the maximum heat observed after death should have been in the thigh, and the minimum in the brain. The post-mortem rise in temperature appears to be esssentially due to the passage of the muscles of the body into the state of rigor mortis, a change that is associated with chemical action analogous to that occurring during contraction, and accompanied by a corresponding elevation of temperature.† Ackermann has pointed out that the post-mortem rise may in part be due to the persistence of the heat-producing chemical changes in the deeper parts of the body, whilst the radiation and loss of heat from the surface by evaporation is reduced by the contraction of the cutaneous vessels and the cessation of the circulation, and Wunderlich suggests that it may be also in some measure owing to the paralysis of that part of the nervous system which inhibits or regulates the generation of heat, supposing such centre to enist.

385. Although there appears to be, for all kinds of animals, a distinct limit to the variations of bodily temperature, under which their vital operations can be carried on, this limitation does not prevent certain species from existing in the midst of great diversities of external conditions; since they have within themselves the power of compensating for these, in a very extraordinary degree. This power seems to exist in Man to a higher amount than in most other animals; since he can not only support, but enjoy life, under extremes of which either would be fatal to many. In some parts of the tropical zone, the thermometer rises every day, through a large portion of the year, to 110°; and in British India it is said to be seen occasionally at 130°. On the other hand, the degree of cold frequently sustained by Arctic voyagers, and quite endurable under proper precautions, appears much more astonishing; by Captain Parry the thermometer has been seen as low as −55°, or 87° below the freezing-point; by Captain Franklin at −58°, or 90° below the freezing-point; and by Captain Back at −70°, or 102° below the freezing-point. In both cases, the effect of the atmospheric temperature on the body is greatly influenced by the condition of the air as to motion or rest: thus, every one has heard of the almost unbearable oppressiveness of the 'sirocco' or hot wind of Sicily and Italy, the actual temperature of which is not higher than has often been experienced without any great discomfort when the air is calm; and on the other side, it may be mentioned that, in the experience of many Arctic voyagers, a temperature of −50° may be sustained, when the air is perfectly still, with less inconvenience than is caused by the air in motion at a temperature 50° higher.‡ This is quite conformable to what might be anticipated on physical principles.

Med.," Band ii. p. 359; Valentin, "Post-mort. Temp.-steigerung Dissert." Leipzig, 1869.

‡ The Author has been informed by Sir John Richardson, that in his last Arctic Expedition,

386. Again, the degree of *moisture* contained in a heated atmosphere, makes a great difference in the degree of elevation of temperature which may be sustained without inconvenience. Many instances are on record of a heat of from 250° to 280° being endured in *dry* air for a considerable length of time, even by persons unaccustomed to a particularly high temperature; and persons whose occupations are such as to require it, can sustain a much higher degree of heat, though not perhaps for any long period. The workmen of the late Sir F. Chantrey were accustomed to enter a furnace in which his moulds were dried, whilst the floor was red-hot, and a thermometer in the air stood at 350°; and Chabert the "Fire-king" was in the habit of entering an oven the temperature of which was from 400° to 600°.* It is possible that these feats might be easily matched by many workmen who are habitually exposed to high temperatures; such as those employed in Iron-foundries, Glass-houses, and Gas-works. In all these instances, the dryness of the air facilitates the rapid vaporization of the fluid, whose secretion by the Cutaneous glandulæ is promoted by heat applied to the surface; and the large amount of caloric which is consumed in this change, is for the most part withdrawn from the body, the temperature of which is thus kept down. By some experimenters, as by Ackermann,† an attempt has been made to show that the lungs as well as the skin constitute a regulating mechanism for preserving an equality of the temperature in warm-blooded animals; since if an animal be exposed to a gradually increasing temperature its temperature rises, but its respirations also increase in number, quite apart from the deficiency of oxygen or increase of carbonic acid in the blood, and ultimately a form of dyspnœa is produced, due simply to heat.‡ The increased number of respirations on exposure to warm air does not, according to Riegel,§ occur in rabbits and dogs in which the spinal cord has been divided high up, and the temperature of the animal continues to rise. In Riegel's experiments on animals under the influence of curare, and in which artificial respiration was maintained, all conditions of the experiment remaining the same, the temperature invariably fell in proportion as respiration was quickened. It is difficult to say whether the power of generating heat which the body possesses is capable of being self-regulated or governed in conformity with the external conditions that may at any time be present; that is to say, whether when the body is exposed to cold more heat is produced, and when to heat, less.

whilst at winter-quarters, he was accustomed to go from his sitting-room to the magnetic observatory at a short distance (about an ordinary street's breadth), without feeling it necessary even to put on a great-coat; although the temperature of the former was about 50°, and that of the air through which he had to pass to the latter was −50°, the difference being 100°. This immunity from chilling influence was chiefly attributable to the *dryness* and *stillness* of the atmosphere; but it is worthy of note that Sir J. Richardson and the whole of his party on this expedition, abstained entirely from alcoholic liquors; and the Author has received his personal assurance that his experience on this occasion fully bore out his previous conviction, that continued severe cold is *much better* borne without recourse to these stimulants than under the employment of them.

* The wonderful feats performed by many individuals from time to time—of dipping the hand into melted lead, laying hold of a red-hot iron, &c.—have been recently shown by M. de Boutigny to be explicable upon very simple principles. For in all such cases a thin film of aqueous fluid in the 'spheroidal state' intervenes between the skin and the heated surface; and a hand which is naturally damp, or which has been slightly moistened, may be safely passed into the stream of *molten iron* as it flows from the furnace; as was demonstrated by M. de Boutigny at the meeting of the British Association at Ipswich in 1851.

§ Virchow's "Archiv," Band lxi. Heft 3.

Liebermeister* found that in a cold bath, or on exposure of the surface to cool air (54°—70° F.), the temperature of the interior of the body in the first instance rose slightly or remained stationary, though it fell after long immersion or exposure. It fell also after removal from the cooling influence. This he explained by considering that the body possesses the power of generating more heat when required, though this power is limited; whilst the secondary fall, when there is no longer any withdrawal of heat, is due to the cooling of the blood circulating in the capillaries of the cool skin. Kering† endeavoured to furnish a further proof by showing that with increase of external heat, or by preventing the body from losing its temperature, a diminished production of heat takes place. Jürgensen‡ and Senator§ oppose these statements, and maintain that when the body is exposed to cold, there is no increased production of heat, but the superficial vessels contract, and a badly-conducting superficial layer of tissue exists, so that the blood in the deeper organs is prevented from giving off its heat, and thus with unaltered production of heat may rise in temperature. As soon as the exposure to cold ceases, the cutaneous vessels dilate, and the blood circulating through the cooled part leads to a fall of temperature. Funke‖ considers that the rapid rise that occurs in the temperature of the body in animals that have been thoroughly cooled, when placed under favourable circumstances, is in favour of Liebermeister and Kering's views. Exposure to intense cold causes a fall of the temperature of the whole body from the first, and *vice versâ* during exposure to a hot bath.¶

387. Exposure to a very elevated temperature, if continued for a sufficient length of time, does produce a certain elevation of that of the body; as might be expected from the statements already made in regard to the variation in the heat of the body with changes in atmospheric temperature (§ 382). Immersion in a hot bath, at the temperature of the body, for an hour, causes a rise of temperature of 1° C. ($1\frac{4}{5}$ deg. F.), and, if continued for another half hour, the temperature of the body rises 2° C. (Liebermeister). So, too, in the experiments of MM. Berger and Delaroche,** it was found that, after the body had been exposed to air of 120° during 17 minutes, a thermometer placed in the mouth rose nearly 7° above the ordinary temperature; it may be remarked, however, that as the body was immersed in a close box, from which the head projected (in order to avoid the direct influence of the heated air on the temperature of the mouth), the air had probably become charged with the vapour exhaled from the surface, and had therefore somewhat of the effects of a moist atmosphere. At any rate, the temperature of the healthy body does not appear to rise, under any circumstances, to a degree very much greater than this. In one of the experiments of Drs. Fordyce and Blagden,†† the temperature of a Dog, that had been shut up for half an hour in a chamber of which the temperature was between 220° and 236°, was found to have risen from 101° to about 108°. MM. Delaroche and Berger tried several experiments on different species of animals, in order to ascertain

the highest temperature to which the body could be raised without the destruction of life, by enclosing them in air heated from 122° to 201°, until they died: the result was very uniform, the temperature of the body at the end of the experiment only varying in the different species between 11° and 13° above their natural standard: whence it may be inferred that a sudden elevation to this degree must be fatal.* This elevation would be attained comparatively soon in a *moist* atmosphere; partly because of the greater conducting power of the medium, but principally on account of the check which is put upon the vaporization of the fluid secreted by the skin. Even here, however, custom and acquired constitution have a very striking influence; for whilst the inhabitants of this country are unable to sustain, during more than 10 or 12 minutes, immersion in a vapour-bath of the temperature of 110° or 120°, the Finnish peasantry remain for half an hour or more in a vapour-bath, whose temperature finally rises even to 158° or 167°. Death occurs in cold-blooded animals on sudden immersion in water at a temperature of from 98° to 102° F., in Mammals, for some minutes at a temperature of 109°—115° F., and in Birds of 120°—122° F. On examining the heart, it is found to have stopped, though it long continues to beat in ordinary asphyxia, and neither it nor any of the striated muscles respond to electrical or other stimuli, whilst cadaveric rigidity, due apparently to coagulation of the myosin, sets in with wonderful rapidity. The fatal effect of exposure to heat is attributed by Bernard† to the toxic influence of heat on striated muscular tissue, which speedily occasions the arrest of the cardiac and respiratory movements. The unstriated muscular fibres seem to be powerfully stimulated by these degrees of heat. The blood is dark and contains little oxygen (1 or 2 per cent.). The hand can with difficulty be borne in water at a temperature of 120° F.: higher temperatures produce acute pain. Pouchet‡ has endeavoured to show that, when small animals are exposed to cold, death results from changes occurring in the blood corpuscles; Walther§ has referred the fatal issue to anæmia of the nervous system. Both Dr. Davy‖ and Pouchet found that completely frozen animals were incapable of being restored to life.—Accurate experiments are yet wanting to determine the influence of humidity on the effects of *cold* air. From experiments on young Birds incapable of maintaining their own temperature, of which some were placed in cold dry air, and others in cold air charged with moisture, it was found by Dr. Edwards that the loss of heat was in both instances the same; the effect of the evaporation from the surface in the former case being counterbalanced in the latter by the depressing influence of the cold moisture. This influence, the existence of which is a matter of ordinary experience, is probably exerted directly upon the Nervous system.

388. Having thus considered the general facts which indicate the faculty possessed by the living system, in Man and the higher Animals, of keeping up its temperature to an elevated standard, and of preventing it from being raised much beyond it by any degree of external heat, we have next to inquire to what this faculty is due.¶—It may be stated as a general fact, that every

* Bernard ("Comptes Rendus de la Société de Biologie," 1859, p. 51) attributes the death of the animals in these and similar experiments to a condition analogous to rigor mortis of the heart being established. He found the auricles filled with blood, but the ventricles firmly contracted and empty.

¶ It was affirmed by Dr. Granville ("Phil. Trans.," 1825) that the temperature of the uterus during parturition sometimes rises as high as 120°. In some observations made at

change in the condition of the organic components of the body, in which their elements enter into new combinations with Oxygen, *must* be a source of the development of Heat. And as we have seen that a considerable part of the carbonic acid and water which are exhaled in Respiration, is formed within the body by the metamorphosis of its own tissues, and that this metamorphosis is promoted by the active exercise of the nervo-muscular apparatus, it follows that in animals whose habits of life are peculiarly active, whilst the temperature of the surrounding medium is sufficiently high to prevent its exerting any considerable cooling influence over them, the combustive process thus maintained may be adequate for the maintenance of the temperature of the body at its normal standard. This seems to be the case with the great Carnivorous quadrupeds of warm climates, and with certain races of Men who lead a life of incessant activity like theirs. But whenever the cooling influence of the atmosphere is greater, or the retrograde metamorphosis of tissue takes place with less activity, some further supply of heat-producing material is required; and this is derived either directly from the food, or from a store previously laid up in the body. Although the albuminous and gelatinous components of the food may be made, by decomposition within the body, to yield saccharine and oleaginous compounds which serve as an immediate *pabulum* to the combustive process (§§ 80, 318), yet this metamorphosis involves a great waste of valuable nutritive material; and the needed supply is much more advantageously derived at once from those farinaceous or oleaginous substances, which are furnished in abundance by the Vegetable kingdom, the latter also by animals. No reasonable doubt can any longer be entertained, that the production of Heat by the combustive process is the purpose to which a large proportion of these substances is destined to be subservient in the bodies of Herbivorous animals and of Man; and the results of experience in regard to their relative heat-producing powers, are in precise accordance with the indications afforded by their chemical composition.
